liver-specific regulation. Binding sites for a number of nuclear regulatory proteins including ARP-1, EAR-2, EAR-3, HNF-4 and C/EBP have been identified within the promoter region. HNF-4 and C/EBP activate transcription synergistically. ARP-1, EAR-2, and EAR-3 repress transcription. There is a core enhancer in intron 2 that binds HNF-1, C/EBP, and an uncharacterized protein. A weaker enhancer lies in intron 3. In addition to these elements, nuclear matrix association regions (MARs), identified at the 5′ and 3′ ends of the gene, have been shown to play an important role in apoB expression. Tissue-specific transcription in liver and intestine correlates with undermethylation of the 5′ flanking region in these tissues.

There is a hypervariable region, composed of 15-bp AT-rich tandem repeats, located 200-bp downstream of the gene, with at least 14 common alleles ranging from 25 to 52 repeats. Five single-amino-acid substitution polymorphisms, the antigenic group (Ag) series, were first detected in antisera from multiply transfused subjects. Four are in association with unique common apoB polymorphisms. In the case of the fifth, the Ag(x/y) polymorphism, two SNPs in complete linkage disequilibrium are involved. These are BfaI and Eco57I RFLPs, associated with P2712L and N4311S substitutions, respectively. Pro2712/Asn4311 represents the more common Ag(y) epitope. A silent XbaI RFLP in the third base of the codon for Thr2488 is in strong linkage disequilibrium with the Ag(x/y) polymorphism. An association of the XbaI RFLP with differences in lipid levels has been reported in a number of studies, with this polymorphism accounting for possibly 3 to 5% of the variance seen in the amount of LDL cholesterol in the general population. A common insertion/deletion polymorphism results in either a 27- or 24-residue signal sequence. A rare third allele has 29 residues. A number of studies have examined the association between particular polymorphisms or haplotypes and either lipid levels or incidence of atherosclerotic disease.

6.7 Apolipoprotein C-I

A minor component of HDL, IDL, and VLDL, apoC-I is found mainly in HDL (97%). More than 90% of the circulating apoC-I is of hepatic origin, with moderate expression in skin and trace levels of expression in brain. Little is known concerning its physiological function. It was shown to be a highly effective inhibitor of the binding of apoE-enriched βVLDL to the α_2-macroglobulin receptor/LRP. The expression of the human *apoC-I* gene in transgenic mice resulted in high levels of triglyceride-rich lipoproteins, indicating that apoC-I is involved in the regulation of their metabolism. Evidence in baboons indicates that an N-terminal fragment of apoC-I interacts with apoA-I to inhibit CETP activity. It may also be a cofactor for LCAT. ApoC-I, which has a domain that binds to lipopolysaccharide seems to play a role in infection and inflammation.

A functional apoC-I promoter polymorphism at −317 (a HpaI RFLP), between the *apoC-I* and *apoE* genes, is associated with type III hyperlipidemia *via* the apoE genotype. There is a synonymous SNP in codon 6, and BglI and DraI RFLPs have been reported. Common liver-specific regulation of expression of the *apoC-I* and *apoE* genes is discussed below (Sect. 6.11). ApoC-I deficient mice produced by gene targeting have a moderately elevated level

of serum triglycerides. The rate of clearance of remnant lipoprotein particles in these animals is decreased.

6.8 Apolipoprotein C-II

The apolipoprotein apoC-II gene is expressed mainly in the liver, with intestinal cells containing only small amounts of mRNA. It is glycosylated within the cell but is subsequently deglycosylated in the plasma, where it exists mainly in the 8.9 kDa, 79-residue form, although some of it is further processed by removal of the N-terminal 6-amino acids to produce a minor isoform. The only known role of apoC-II is as the requisite cofactor for LPL. The activator and primary LPL binding domains are located in the C-terminal third of apoC-II. Like the other C apolipoproteins, apoC-II is transferred during hydrolysis from chylomicrons and VLDL to HDL. Most of the circulating apoC-II is present in HDL; 10% is in IDL, and 30% is in VLDL and chylomicrons.

The first intron of the *apoC-II* gene contains 4 Alu type sequences and a $(TG)_n(AG)_m$ microsatellite with at least 15 different alleles. The third intron contains a minisatellite composed of 37-bp tandem repeats. There are two common alleles of six and seven repeats with frequencies of 82 and 18%, respectively. AvaII, BanI, BglI, NcoI, PstI, and TaqI, RFLPs have been reported. In human hepatoma cells, apoC-II is upregulated by the nuclear receptor FXR.

Three charge variants of apoC-II, K19T, E38K, and K55Q, all detected by isoelectric focusing, have been reported. The first two are rare, but the K55Q variant is common among individuals of African decent. Whether they are associated with hyperlipidemia is unclear.

6.8.1 Apolipoprotein C-II Deficiency

Autosomal recessive familial chylomicronemia, due to homozygous apoC-II deficiency, has been described in ten instances. It is characterized by fasting chylomicronemia and severe hypertriglyceridemia, and is often accompanied by the presence of xanthomas and pancreatitis. Six cases were due to apoC-II gene mutations that introduced premature stop codons, resulting in either the absence of apoC-II or very low levels of truncated species. One other was due to an intron 2 donor splice defect, and one to an initiation defect M-22V. In one case, a single C insertion between codons 69 and 70 resulted in low levels of a 96-residue frameshifted protein with severely impaired cofactor activity. A major disruption of the *apoC-II* gene, and neighboring *apoC-IV* gene, by a 7.5-kb deletion, has also been reported.

6.9 Apolipoprotein C-III

The glycoprotein, apoC-III is the most abundant protein in VLDL after apoB100, comprising 25 to 30% of the protein mass. Most is found in HDL (60%), 10% in LDL, 10% in IDL and 20% in VLDL. There are three isoforms: apoC-III_{-0}, apoC-III_{-1} and apoC-III_{-2}, with 0, 1, and 2 residues of sialic acid per molecule, respectively. These have different isoelectric points and can be separated by isoelectric focusing.

Little is known about the precise function of apoC-III in lipoprotein metabolism. It inhibits LPL *in vitro*. Although a number of hydrophilic sequences within the peptide interact with LPL, the major inhibitory effect resides in an NH_2 terminal domain. ApoC-III does not compete with apoC-II at the apoC-II activation site on LPL. Glycosylation of apoC-III does not seem to be important for LPL inhibition.

Overproduction of VLDL in rats fed a high-sucrose diet does not alter the rate of apoC-III gene transcription, or the level of mRNA, in liver. Inflammation is linked to a reduction in the level of hepatic apoC-III mRNA and with a decrease in circulating HDL apoC-III content. Thyroid hormone has been reported to improve the efficiency of maturation of the apoC-III mRNA.

Studies using transgenic mice suggest that apoC-III is involved in the apoE-mediated clearance of triglyceride-rich lipoproteins. Overexpression of the human gene in transgenic mice causes elevated levels of VLDL triglyceride with more than double the normal amount of apoC-III per particle, and is accompanied by an increase in circulating nonesterified fatty acids. The VLDL particles have a larger mean diameter and are taken up poorly by lipoprotein receptors. Tissue levels of LPL are normal and it is likely that the hypertriglyceridemia is a result of the low fractional catabolic rate of VLDL and a low rate of clearance of apoB48 remnants in these animals. This low rate is probably due to the combined effect of the increased amount of apoC-III and the decreased amount of apoE, on VLDL. These mice were crossed with those that overexpress apoE to produce animals overexpressing both apoC-III and apoE. These animals had normal levels of triglycerides and chylomicron remnants.

ApoC-III deficient mice, produced by gene targeting, have decreased fasting levels of triglycerides and show an absence of postprandial lipemia with an increased rate of clearance of chylomicrons. An interpretation of these findings is complicated by the fact that the intestinal expression of the neighboring *apoA-I* and *apoA-IV* genes are decreased in these animals.

In a family of Mexican origin an apoC-III Q38K mutant was associated with moderate hypertriglyceridemia. Rare variants, D45N and A23T do not seem to be associated with dyslipidemia. Another mutant, T74A, is not glycosylated. Hyperalphalipoproteinemia with abnormal HDL containing large apoE-rich particles was seen in subjects with an apoC-III K58E mutation. There is an SstI SNP in the 3′ untranslated region of exon 4 and a tetranucleotide repeat polymorphism, with 7 common alleles, in intron 3, at the end of an Alu sequence. The SstI SNP and a polymorphism in a promoter insulin response element are associated with differences in triglyceride levels.

6.10 Apolipoprotein C-IV

That an additional apolipoprotein gene might exist at the 19q13.2 locus along with *apoC-I*, *apoC-II*, and *apoE* was first suggested in a study of the corresponding rat locus. Later, the human *apoC-IV* gene was characterized and shown to be located only 555-bp upstream of *apoC-II*. It lacks a TATA box and is transcribed in liver at a level well below that of the *apoC-II* gene. A higher expression level of apoC-IV in the rabbit has been attributed to the presence of a unique purine-rich tandem repeat sequence in the promoter and 5′ UTR that functions as a GAGA box. The peptide has two amphipathic α-helical regions and has but a limited homology with apoC-I, apoC-II, and apoE. Very low levels of apoC-IV are found in human plasma, mainly in VLDL with some in HDL. Much higher levels of the protein are found in rabbit plasma, where it is primarily associated with VLDL particles. Rabbit apoC-IV was the first to be characterized. The human protein can be O- and N-glycosylated, and exists as a number of sialylation isoforms. When the human protein was expressed

in mice there was an associated increase in plasma levels of triglyceride.

6.11 Apolipoprotein E

ApoE mRNA is found in a number of tissues, notably liver, brain, kidney, adrenal gland, macrophages, spleen, and ovary. The sequence between residues 140 and 160 of the mature peptide constitutes the ligand that binds to the LDL receptor. The C-terminal residues 245 to 299 are important for the association of apoE with lipoprotein particles and for tetramer formation. Most of the apoE in the circulation is synthesized in the liver. Much of the newly synthesized apoE, like apoB, is broken down by a degradative pathway. The synthesis and secretion of apoE is reduced by insulin. Half of the apoE present in serum is in HDL, 10% in LDL, 20% in IDL, and 20% in VLDL. It is a glycoprotein with a single O-linked chain at Thr194. The carbohydrate contains one or more sialic acid residues.

There are three common alleles of the apoE gene, $\varepsilon 2$, $\varepsilon 3$, and $\varepsilon 4$, present at frequencies of 9, 77, and 14%, which give rise to E2, E3, and E4 isoforms, respectively. The proteins can be separated by isoelectric focusing, with E4 the most basic, and E2 the most acidic. They differ at residues 112 and 158. E2 is Cys112/Cys158, E3 is Cys112/Arg158 and E4 is Arg112/Arg158. Some of the E3 in plasma exists as a homodimer and some as a heterodimer with apoA-II. The binding affinity of E2 for the LDL receptor is less than 5% that of E3 or E4. This is thought to be due to reorganized salt bridges as a result of the loss of the Arg158 residue. This changes the charge disposition of the surface that is presented to the receptor.

Expression of apoE in liver in transgenic mice was shown to require the presence of a hepatic control region (HCR) located 18-kb and 9-kb downstream of the *apoE* and *apoC-I* genes, respectively. This HCR lies between the *apoC-I* gene and the *apoC-I* pseudogene. Constructs containing a 5-kb apoE promoter but lacking the HCR resulted in expression only in kidney and skin. A second HCR was later located 27-kb downstream of the *apoE* gene. The four genes in the 19q13.2 cluster, *apoC-I*, *apoC-II*, *apoC-IV*, and *apoE*, are coordinately regulated. In liver, this regulation is *via* the two distal 350-bp HCRs (HCR.1 and HCR.2), which show close homology. In macrophages, adipose tissue, brain, and skin regulation is through two homologous 620-bp multienhancer regions (ME.1 and ME.2) situated 3.3-kb and 15.9-kb downstream of the *apoE* gene, respectively. ME.1 and ME.2 contain LXR response elements, and in macrophages the mRNAs for all four genes were upregulated in response to LXR ligands. It has been hypothesized that the induction of these four genes may be important for promoting the efflux of lipid from macrophage foam cells in atherosclerotic lesions.

Transgenic mice that overexpress apoE have a striking decrease in plasma levels of VLDL and LDL due to increased clearance rates of triglyceride-rich lipoproteins.

Homologous recombination was used to target and inactivate the *apoE* gene in mice. These $Apoe^{-/-}$ animals have hypercholesterolemia, which is especially severe when they are fed a high fat diet. Plasma levels of VLDL and VLDL remnants, containing mainly apoB-48 rather than apoB-100, are raised. The mice exhibit rapid development of atherosclerotic lesions that are thought to be a result simply of the very high cholesterol levels (400

to 500 mg dL^{-1}) rather than to the atherogenicity of the VLDL and VLDL remnant particles. Mice resulting from crossing *Apoe*$^{-/-}$ mice with those that exclusively produce apoB-100 (*Apob*$^{100/100}$ mice) had lower levels of total cholesterol, similar to the levels in *Ldlr*$^{-/-}$ mice crossed with *Apob*$^{100/100}$ mice. The latter animals had much more severe atherosclerosis due to higher numbers of small LDL.

The abnormal phenotype of *Apoe*$^{-/-}$ mice was to a large extent corrected following bone marrow transplantation from a donor mouse with the normal *apoE* gene, indicating the extent to which apoE synthesized by macrophages can contribute to the pool of lipoprotein apoE.

6.11.1 Dysbetalipoproteinemia and ApoE Deficiency

The 1% of individuals who are homozygous for the $\varepsilon 2$ allele have a tendency to accumulate βVLDL in plasma. Additional unknown genetic or other factors cause 5% of these subjects to develop clinically important dysbetalipoproteinemia with marked accumulation of chylomicron and VLDL remnants. This disorder is referred to as *type III hyperlipidemia*.

Rare isoforms of apoE have been discovered, many of which are defective in binding to the LDL receptor. In four of these cases the mutation results in dominant transmission, and in one case recessive transmission, of type III hyperlipidemia. A double mutant, apoE-$4_{\text{Philadelphia}}$ (E13K and R145C) is associated in the homozygous state with a severe form of type III hyperlipidemia and in the heterozygous state with a moderate form. Transgenic mice have been produced that express the human mutant $\text{apoE}_{\text{Leiden}}$, which contains a seven-amino acid insertion that is a tandem repeat of residues 121 to 127. In these animals there is dominant transmission of hyperlipoproteinemia, characterized by elevated levels of VLDL and LDL.

ApoE deficiency is a rare genetic disorder characterized by less than 1% of normal levels of apoE in plasma. Patients have xanthomas, type III hyperlipidemia and premature atherosclerosis. There is delayed clearance of chylomicron and VLDL remnant particles, leading to elevated levels of cholesterol-rich VLDL and IDL.

6.11.2 Alzheimer Disease and ApoE

The frequency in the population of the $\varepsilon 4$ allele declines with age and that of the $\varepsilon 2$ allele increases. There is much evidence for a highly significant genetic association between the $\varepsilon 4$ allele and late onset Alzheimer's disease (LOAD), both in the familial and the sporadic forms. The effect is proportional to gene dosage, with the $\varepsilon 4/\varepsilon 4$ genotype being a greater risk factor than the $\varepsilon 4/\varepsilon 3$ or $\varepsilon 4/\varepsilon 2$ genotypes. These, in turn, are greater risk factors than the other genotypes ($\varepsilon 3/\varepsilon 3$, $\varepsilon 3/\varepsilon 2$ or $\varepsilon 2/\varepsilon 2$). In families with late-onset Alzheimer's disease, the presence of the $\varepsilon 4/\varepsilon 4$ genotype alone is associated with the disease in almost all of those over 80 years of age. Additional evidence, supporting the link between apoE and Alzheimer's disease, is that the gene locus is in a region of chromosome 19, previously associated with LOAD. The apoE protein has been found in senile plaques and neurofibrillary tangles along with the β-amyloid protein. *In vitro*, both apoE4 and apoE3 bind with high specificity, and irreversibly, to β-amyloid, with apoE residues 244 to 272 being crucial for the interaction. The formation of the complex of β-amyloid with apoE4 is much more rapid than with apoE3.

6.12 Apolipoprotein (a)

Apolipoprotein (a) [apo(a)], synthesized in the liver, is found on a lipoprotein species Lp(a), where it is covalently attached to apoB *via* a disulfide bridge. The two proteins also interact noncovalently. Lp(a) floats in the 1.050 to 1.080 g mL^{-1} density fraction in the ultracentrifuge and can be separated from HDL by gel filtration. The level of Lp(a) within the population varies from less than 0.10 mg dL^{-1} to as much as 500 mg dL^{-1}. Of this variation, 90% is genetically determined, primarily at the *apo(a)* gene locus with a small amount possibly attributed to the *apoE* genotype. One factor that affects the plasma concentration is the size of a particular isoform, with an inverse correlation between the size and the rate of secretion, this rate being determined by the efficiency of posttranslational processing.

High levels of Lp(a) have been shown, in most epidemiological studies, to be an independent risk factor for premature atherosclerosis, but the physiological function of Lp(a) is still essentially unknown, although the high degree of homology of apo(a) with plasminogen appears to be responsible for its inhibitory effect on thrombolysis. Plasminogen and apo(a) compete in binding to fibrin. Recombinant apo(a) binds with high affinity *via* intrachain lysine residues of intact fibrin and to carboxy-terminal lysines on the degraded peptides. To what degree Lp(a) inhibits fibrinolysis physiologically has been questioned. It has been postulated that Lp(a), *via* a reduction in the formation of plasmin, enhances vascular smooth muscle cell proliferation as a result of lower activation of TGFβ.

Thyroid hormone status, besides modulating the plasma concentration of total apoB also affects Lp(a) levels. In the hypothyroid state, there is impaired catabolism. Secretion is suppressed and catabolism elevated in the hyperthyroid state.

It is not clear to what extent Lp(a) is secreted directly from the liver or formed in plasma as a result of association between free apo(a) and LDL. It does not appear to originate from a triglyceride-rich lipoprotein precursor. Contact with LDL is made through only a few kringle repeats with most of the apo(a) extended away from the particle.

The human gene for apo(a), *LPA*, is closely linked to that of plasminogen (*PLG*), the two genes being separated by 38 kb. Two *apo(a)*/plasminogen pseudogenes are present at the same locus. The size of the *apo(a)* gene is highly polymorphic and depends on the number of exons that code for tri-loop peptide structures held together by three internal disulfide bonds and termed *kringles*. Plasminogen has five kringles numbered I to V. Apo(a) has a variable number of kringles, with high homology to plasminogen kringle IV, and a single copy homologous to kringle V. It also has a region that is homologous to the plasminogen protease domain, but it does not have a tissue plasminogen activator cleavage site. Cys4057, in kringle 36 of the published cDNA sequence, one of the kringle IV repeats, forms a disulfide bond with apoB Cys4326. In the noncovalent interaction, apoB lysine 680 plays a critical role. The size polymorphism, which is reflected in the molecular weight range (<300 to >800 kDa) of more than 34 different apo(a) isoforms, can be detected by pulsed-field gel electrophoresis after digestion with KpnI. In addition to these size

polymorphisms, 14 SNPs have been reported. There is a common Met to Thr polymorphism in kringle IV type 10. A Trp-to-Arg mutation, also in kringle IV type 10, results in Lp(a) that is defective in binding to the lysine residues of fibrin. A C/T polymorphism in the 5′ untranslated region of the gene is associated with decreased *in vitro* translation.

When fed a high-fat diet, transgenic mice (a species in which Lp(a) is absent) that express human apo(a) had larger areas of lipid-staining atherosclerotic lesions than control animals did. The apo(a) in these animals is not in the form of Lp(a); that is, it is not covalently attached to apoB. However, when these mice were crossed with mice expressing human apoB100, high levels of human Lp(a) were found in the plasma.

6.13 Other Apolipoproteins

6.13.1 Apolipoprotein D

The sialoglycoprotein apoD is related to retinol-binding protein and both are members of the lipocalin superfamily. ApoD shows no homology with the other apolipoproteins. In humans, the gene is expressed in a number of tissues, notably the adrenal glands, cerebellum, spleen, kidney, and pancreas. There is much less expression in the liver and intestine. Cleavage of the 20-residue signal peptide gives rise to the mature form in which the N-terminal Gln is blocked by cyclization. Much of it exists as a 38-kDa heterodimer with apoA-II. Isoelectric focusing detects a number of isoforms with variable numbers of sialic acid residues. It is mainly found in the HDL fraction where it constitutes about 5% of the total protein. It binds to a number of ligands, including progesterone, cholesterol, bilirubin, and arachidonic acid. ApoD possibly plays a role, alongside LCAT and CETP in reverse cholesterol transport. There is increasing evidence that apoD is important for nerve regeneration.

Putative regulatory domains have been reported in the apoD promoter region. Response elements include those for estrogen, progesterone, glucocorticoid, and thyroid hormone. The promoter contains a 26-bp element that could form a Z-DNA structure. MspI and TaqI RFLPs have been studied.

6.13.2 Apolipoprotein H

The physiologic function of apoH has not been determined with any certainty. It is also referred to as *beta-2-glycoprotein I*. In addition to being involved in lipoprotein metabolism, it has also been reported to be involved in coagulation, and is a cofactor for the binding of antiphospholipid autoantibodies to anionic phospholipid. These antibodies are found, for example, in patients with lupus erythematosus. The gene for apoH is alternatively spliced and probably produces a number of distinct polypeptide products.

6.13.3 Apolipoprotein J

An abundant and widely dispersed glycoprotein, ApoJ, also referred to as *clusterin* and *SP-40/40*, is expressed at a high level in the epithelial cells of many tissues. A constituent of the terminal complement complex, apoJ is a multifunctional glycoprotein that inhibits complement-mediated cytolysis. It is found on an unstable subclass of HDL particles that have $\alpha 2$ electrophoretic mobility, only a small proportion of which contain apoA-I. ApoJ and apoA-I associate *in vitro*. ApoJ is an inhibitor of the complement membrane-attack complex. ApoJ is

stored in platelet granules and released after platelet activation, and it may be involved in wound repair. The other functions of apoJ are thought to include roles in sperm maturation, lipid transport, programmed cell death, and membrane recycling.

6.13.4 Apolipoprotein L Gene Family

ApoL-I, reported to be the trypanosome lytic factor, was discovered on a subpopulation of HDL particles in HDL isolated by selected-affinity immunosorption. The gene for apoL-I is a member of a family of six genes; however, only apoL-I seems to be truly an apolipoprotein. Microarray analysis of prefrontal cortex tissue from schizophrenia subjects showed upregulation of the *ApoL-I, ApoL-II,* and *ApoL-IV* genes.

7 Scavenger Receptors

7.1 SR-BI/CLA1

The scavenger receptor class B type I, SR-BI, which binds directly to cholesterol, is able to alter the distribution of membrane cholesterol pools, and is localized to cholesterol-rich rafts. It facilitates the selective uptake by the liver of cholesteryl esters from HDL, thereby playing a crucial role in reverse cholesterol transport. SR-BI binds through a C-terminal domain to the multifunctional PDZK1 protein, which may play a scaffolding role. PDZK1 knockout mice have increased serum levels of cholesterol.

Previously, it was thought that initial binding of HDL to the receptor was followed by diffusion of lipid into the plasma membrane down a concentration gradient. It is now believed that, following binding to SR-BI, the complete HDL particle undergoes endocytosis. The cholesteryl esters are hydrolyzed in early endosomes and the HDL particle is then recycled to the plasma membrane and secreted. SR-BI expression correlates with the secretion of cholesterol into bile, SR-BI being expressed in canalicular as well as sinusoidal membranes. Hence, it is thought that SR-BI helps to mediate the secretion of cholesterol into bile, possibly in conjunction with phospholipid transporters such as ABCB4 and sterol transporters ABCG5/G8. In peripheral tissues, SR-BI mediates the diffusion of free cholesterol from the plasma membrane to *alpha* HDL particles. In macrophages, it plays an important antiatherogenic role.

The human gene for SR-BI (also known as *CLAI* and *CD36L1*) is *SCARB1* and is located at chromosome 12q24.31. It spans 86 kbp and has 13 exons. It codes for a 509-residue, 57-kDa, protein, which is N-glycosylated at a number of sites, giving a total molecular weight of 82 to 86 kDa. Both the N- and C-termini are located in the cytoplasm with two transmembrane domains separated by a 408-residue extracellular domain. As a result of alternative splicing, there is a second isoform called *SR-BII,* with a different C-terminus.

7.2 Modified LDL Receptors: MSR1, CD36 and LOX1

Oxidized or chemically modified LDL are taken up by macrophages *via* receptor-mediated endocytosis, independent of the LDL receptor. This may be the mechanism, *in vivo*, for foam cell formation, leading to atherosclerotic lesions. Lipoproteins containing apoB have been

isolated from normal and atheromatous arteries.

Initially, from bovine liver, a glycoprotein was isolated that binds to acetylated LDL, oxidized LDL, and endotoxin (bacterial lipopolysaccharide), and was referred to as the *acetylated LDL receptor* or *scavenger receptor*. The ligands for this receptor are numerous and include polyanionic compounds, such as polyribonucleotides. Cloning of the receptor, SR-A, now referred to as the *macrophage scavenger receptor 1 (MSR1)*, revealed the presence of two homologous proteins, the type I and type II class A scavenger receptors. These are produced from a single MSR1 gene by alternative splicing. The human gene at chromosome 8p22 has 10 exons. Isoform type I has 451 residues (50 kDa) and type II 388 residues (38 kDa). They have identical structures except for the C-terminus. The common structures include an NH_2-terminal cytoplasmic tail, a transmembrane region and a collagen-like domain. The active receptors exist as trimers. A third isoform exists, that does not internalize acetyl-LDL and by inhibiting the first two isoforms plays a dominant negative function. Despite increased foam cell formation in cells overexpressing MSR1 *in vitro*, decreased atherosclerosis was observed in MSR1 transgenic mice.

The macrophage receptor, CD36, was found to bind oxidized LDL with high affinity. It belongs to the family of class B scavenger receptors, which includes SR-BI and LIMP-2. CD36 is a multifunctional receptor that is also referred to as the *collagen type I receptor*, and the *thrombospondin receptor*. In phagocytic cells, it is a scavenger receptor that recognizes and removes apoptotic cells. Among the numerous roles attributed to it, CD36 is also thought to function as a fatty acid translocase (FAT) in muscle and adipose tissue. CD36 knockout mice develop hyperlipidemia, and transgenic animals develop hypolipidemia. Supporting the notion that CD36, as a scavenger receptor for oxidized atherogenic lipoproteins, is of major importance in the development of atherosclerosis are data with CD36 knockout mice crossed with apoE-deficient animals. These animals, when put on a high fat diet, developed greatly decreased aortic lesions.

The *CD36* gene has 16 exons, spans 38 kbp, and is located on chromosome 7q21.11. It encodes a 471-amino acid-residue transmembrane protein that is highly glycosylated. Feed-forward upregulation of the *CD36* gene by oxidized LDL is *via* a PPARγ response element in its promoter that is activated by PPARγ ligands such as prostaglandin J2. CD36 is also induced by interleukin-4. During inflammation, it is downregulated *via* TGF-β1 and lipopolysaccharide.

A member of the C-type lectin gene family, the oxidized LDL (lectin-like) receptor 1 (OLR1), also referred to as *LOX1*, has been shown to bind and internalize oxidized LDL. The *OLR1* gene is located on chromosome 12p13.2 with a cluster of natural killer cell receptor genes. Its six exons span 14 kb, and encode a 273-residue protein. It is expressed in a number of tissues, including brain, testis, kidney, and aorta, with the highest levels of mRNA in lung, spinal cord, and placenta. OLR1 is upregulated by a number of cytokines. Case-control studies indicate that polymorphisms at the OLR1 locus are associated with risk of CAD and acute myocardial infarction. There have been conflicting reports on associations with Alzheimer disease.

8
Lipids and Atherosclerosis

Disorders in the transport and metabolism of lipids contribute materially to the development of arteriosclerotic heart disease, stroke, and peripheral vascular disease. The histological hallmark of atherogenesis is the lipid-filled macrophage, which is transformed into a proinflammatory element. Smooth muscle cells can also be transformed into lipid-filled cells that participate in atherogenesis. The accumulation of oxidized lipids leads to the formation of neoantigens and increases oxidative stress, evoking an array of inflammatory mechanisms, ultimately leading to the attenuation of coronary blood flow or its cessation in some regions of the coronary vasculature, resulting in myocardial infarction.

The cell biology of these processes is highly complex, involving many factors that reflect genomic dependency. Rapid progress in the study of the genomic basis of disorders of lipid metabolism and of coronary disease is leading to the investigation of novel genes, thereby opening new avenues for understanding of the mechanisms underlying vascular diseases.

Keywords

Ceramide
A branched chain lipid based on a long-chain (C_{18}) polyhydroxyamine (= sphingolipid) to which a fatty acid group is attached via the 2-amino group.

Fatty Acids
Long-chain (usually 16 or 18C atoms) aliphatic carboxylic acids normally found esterified to glycerol; see **Triacylglycerol**.

Glycolipid
A sugar (usually a mono- or disaccharide) linked to one or more fatty acyl groups; acts as an emulsifying agent by having both water- and lipid-soluble components.

Lipoglycan
A macromolecular complex where the glucan or glycan (polysaccharide) backbone molecule has a number of fatty acyl substituents. Overall, the molecule retains its carbohydrate properties.

Neutral Lipid
A lipid having no charged group; encompasses mono-, di-, and triacylglycerols plus hydrocarbons, including carotenoids, sterols, and so on.

Phospholipid
Strictly, any lipid containing a phospho group, but usually refers to lipids based on 1-, 2-diacyglycerol-3-phosphate (also known as *phosphatidic acid*); a polar substituent (often choline) may also occur on the phospho group, thereby creating a range of phospholipid types. Phospholipids form the major component of most membranes of cells.

Polar Lipids
A lipid having a polar (charged) group; often taken to be synonymous with phospholipids but will include sphingolipids and other related lipids.

Polyunsaturated Fatty Acids (PUFA)
Fatty acids containing three or more double bonds that are usually methylene interrupted, namely, $-CH{=}CH-CH_2-CH{=}CH-$. Polyunsaturated fatty acids can

therefore be designated according to the position of the double bond nearest to the CH_3-terminus: thus, $CH_3-CH_2-CH=CH-$would be known as an ω-3 (or n-3) fatty acid.

Sulfolipid
Any lipid containing a sulfo group, usually $-SO_3-$.

Terpenoid Lipids
Lipids that are based on multiples of the isopentenyl group (CH_2:C(CH_3)·CH_2·CH_2-) giving rise to sterols, carotenoids, polyprenols, and the side chains of chlorophylls, quinones, and so on.

Triacylglycerol
Member of a class of lipids in which the three alcohol groups of glycerol ($CH_2OH·CHOH·CH_2OH$) are each esterified with a fatty acid. These, along with phospholipids, are the predominant lipid types in most eukaryotic cells.

Unsaturated Fatty Acids
Fatty acids containing one or more double ($-CH=CH-$) bonds. The position of the double bond is indicated by the first carbon numbering from the carboxylic acid group: $^{1}COOH·^{2}CH_2·^{3}CH_2·^{4}CH_2·^{5}CH_2·^{6}CH_2·^{7}CH_2·^{8}CH_2·^{9}CH=^{10}CH·^{11}CH_2·^{12}CH=^{13}CH·^{14}CH_2·^{15}CH_2·^{16}CH_2·^{17}CH_2·^{18}CH_3$ is 9, 12-octadecadienoic acid (or linoleic acid). The orientation of the double bond is usually in the *Z* (or cis) configuration though *E* (or trans) bonds are known. The shorthand nomenclature for the acid above is therefore 18 : 2 (*Z*9, *Z*12), abbreviated to 18 : 2 (9, 12) if the stereospecificity is not required to be stated. Sometimes it is convenient just to give the position of the double bond nearest the terminal methyl group because, once this is defined, the position of all the other double bonds, being methylene interrupted, are also defined: thus linoleic acid could be given as 18 : 2 (ω-6) or alternatively as 18 : 2 (n-6). This system is particularly useful for polyunsaturated fatty acids and is used in this chapter. Almost all double bonds in naturally occurring fatty acids are of the *Z*- or cis configuration.

Microorganisms, like all other living cells, contain lipids. These lipids are probably the most diverse of all the major kingdoms, and range from simple fatty acids as occurring in plants and animals, to complex multibranched ether lipids found only in the most primitive of bacteria, the *Archaea*. Lipids are used for both structural and functional activities. The former include the principal component of all membranes – whether it is of the cytoplasm or of the major organelles of the eukaryotic microorganisms: yeasts, fungi, and algae. The functional aspects of lipids include their role as storage reserve materials as well as fulfilling key roles in photosynthetic microorganisms. Both bacteria and eukaryotic microorganisms have the propensity to accumulate during periods of carbon nutrient excess large

amounts of lipids, which they can utilize during periods of starvation as sources of carbon, energy, and even water. Present biotechnological applications of microbial lipids are aimed at realizing their potential in the nutritional and health care industries. The molecular biology of lipids, though, is a relatively neglected area but is likely to become a major focus of activity as the exploitability of microbial genes for the improvement of plant oils and fats is recognized.

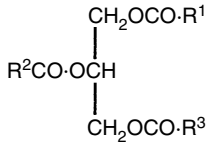
1 Introduction

Lipids are divided into two major classes: the components based on fatty acids (or fatty acyls) and those based on the terpene, or isoprenoid structure. The former includes all the triacylglycerols (**I**) and acylglycerophospholipids (**II**) that occur throughout all eukaryotic cells, including plants, animals as well as microorganisms except the *Archaea*. The latter class of lipids includes the sterols (**III**) and carotenoid (**IV**) lipids, which are synthesized from a common pathway known as the mevalonate or isoprenoid (**V**) route. The archaeal lipids (see Sect. 2) are also derived from mevalonate. Fig. 1 shows the biosynthetic origins of these two groups.

A further distinction that can be made with lipids is to categorize them as polar or neutral. Polar lipids, which are characteristically the lipids of the cell bilayer membranes, owe their polarity to the presence of a charged group such as ethanolamine or choline, attached to the glycerol group (**II**). These lipids are therefore often referred to as phospholipids, an ambiguous and somewhat imprecise term that merely denotes any lipid containing a phospho group. Other polar lipids that do not contain a phospho group include a number of glycolipids, involving condensation of a fatty acid with a sugar or sugar groups, sulfolipids where a SO_3^- group can be found, peptidolipids involving one or more amino acids, and a number of sphingolipids that are more usually thought of as animal-type lipids, but are found in small but significant amounts in many yeasts and fungi. The entire subject of microbial lipids, including lipids of viruses, has been covered in an extensive two-volume treatise edited by the present author and his colleague, Professor S. G. Wilkinson.

Microorganisms are now divided into three domains: *Archaea, Bacteria*, and *Eukarya*. The first two comprise all the prokaryotic organisms that were originally referred to as the *Archaebacteria* and the *Eubacteria*, respectively, and have been combined under the single order of the *Bacteria*. In view of the considerable disparity between the 16S rRNA sequences and the structures of RNA polymerases of these two orders, they are now considered to be distinct evolutionary groups and, therefore, have been given equal ranking. The *Eukarya* domain comprises a group of microorganisms loosely known as the fungi, which are then divided into the yeasts and the molds as useful, but somewhat imprecise terminologies. *Eukarya* also includes the photosynthetic algae. Blue-green algae are now referred to as cyanobacteria and are included in *Bacteria*.

The genetics and molecular biology of microbial lipids is very much in its



where R^1CO-, R^2CO- and R^3CO- are fatty acyl groups.

infancy and only a few areas have received much attention. The application of genetic techniques have mainly been confined to *Escherichia coli* and *Saccharomyces cerevisiae*, neither of which produces unusual or interesting lipids. Nevertheless, the basis of a genetic understanding of microbial lipids has now been laid. This article is aimed at providing factual information concerning the diversity of lipid molecules found in the different major groups of microorganisms.

2 Archaea (or Archaebacteria)

The distinction between the *Archaea*, the most primitive of the prokaryotic domains, and the *Bacteria* was made principally on the differences in the 16S rRNA sequences. This distinction is also clearly seen in the nature of the lipid components of the two domains. The *Archaea* uniquely contain lipids that are made up of repeating isopentanyl (**VI**) units. The isopentanyl

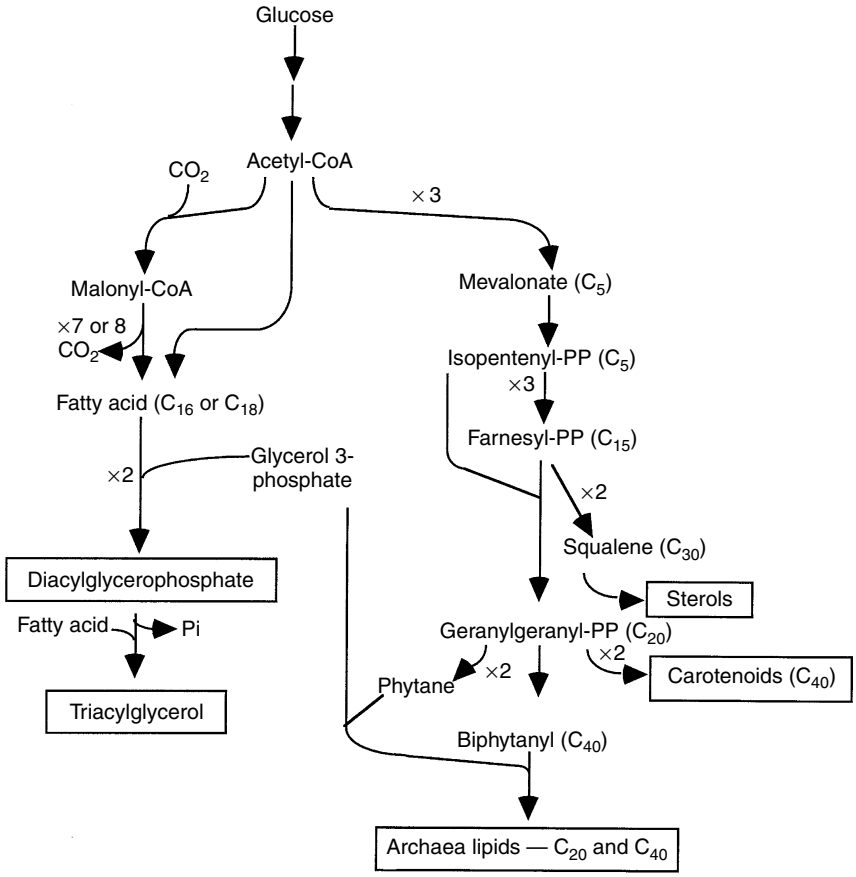

Fig. 1 Biosynthetic origins of major groups of microbial lipids.

unit is derived from the mevalonate pathway of lipid biosynthesis (see Fig. 1), but although this pathway is found in other microorganisms as a source of the terpenoid lipids, in the *Archaea* the entire lipid family are derived from this source.

VI

A further distinction that arises between the archaeal lipids and those of all other organisms is that they are linked to glycerol via ether linkages ($-CH_2-O-CH_2-$) rather than the more common ester link ($-CH_2-O-CO-$). The ether bond is much less susceptible to hydrolysis than the ester linkage and, not surprisingly, then confers considerable stability to the membrane structures of the *Archaea* that are made up with these lipids. The *Archaea* are, indeed, very resistant to extremes of the environment: they comprise the extreme halophiles (*Halobacterium, Halococcus, Natronococcus, Natronobacterium*, and so on), extreme thermophiles (*Thermus, Caldariella, Sulfobolus*, and so on), and organisms that can grow on methane – the methanotrophs

or methanogens (*Methanospirillum*, *Methanosarcina*, *Methanococcus*, and so on). The somewhat loose term ''extremophile'' has been given to this group of organisms as a convenient epithet, but it lacks the formal precision of *Archaea* and may often be used to include representatives of the *Bacteria* that show some tolerance to the extremes of the environment.

A further point to note in connection with these glycerol diether lipids (Fig. 2) is that the two isopranoid chains (also called *phytanyl chains*) are attached to the *sn*2- and 3- positions of glycerol rather than the conventional 1- and 2- positions of the diacylglycerols and diacylphosphoglycerols found in all other living cells, including bacteria.

Typical isopranoid ether lipids of *Archaea* are shown in Fig. 2. The lipid given in Fig. 2(a), which is the core lipid of the *Archaea*, is also referred to as *archaeol*, which indicates its association with this domain of microorganisms as well as its status as an alcohol. The lipid given in Fig. 2(c) is known as *caldarchaeol*. As Fig. 2 indicates, not only are there a variety of configurations giving rise to both diethers and tetraether lipids but there are also phosphoglycolipids and sulfolipids, as well as lipoglycans that form part of the cell wall of these microorganisms and are all composed of these phytanyl lipids.

Thus, not only are the lipid membranes of the extremophilic microorganisms composed of highly stable isopranoid ether lipids but so too are many of the lipid components associated with the cell wall.

Figure 3 gives the biosynthesis of the archaeol phospholipids and glycolipids in the extreme halophiles. The C_{20} product of the mevalonate pathway, probably, geranylgeranyl pyrophosphate is considered to condense with dihydroxyacetone and gives a ''pre-diether.'' This becomes the precursor of both the phospholipids and the glycolipids, with the reduced, unsaturated bonds of the geranylgeranyl group being saturated after condensation with the dihydroxyacetone. The biphytanyl (C_{40}) chains are thought to arise by direct head-to-head condensation of two molecules of archaeol (Fig. 2a). The substituted glycerol and phosphoglycero lipids (Figs. 2e and f) are probably synthesized before this condensation reaction; this would include the sugar-containing lipids (glycolipids).

The function of these branched chain ether lipids is to impart stability to the membranes of these bacteria under extremes of temperature, pH, salinity, and so on. Under these extreme conditions, conventional ester-linked lipids would quickly hydrolyze; moreover, unsaturated fatty acyl groups would be quickly oxidized, and thus, ''conventional'' microorganisms would not, and cannot, survive under these conditions. Since the alkyl chains are completely saturated and furthermore have only short side chains (methyl groups), which allows for close molecular packing, the branched chain ether lipids become liquid crystalline at ambient temperatures. Consequently, their presence in the extreme thermophilic organisms means that these organisms are unable to function until the temperature is at least 70 or even 80 °C. Thus, the high stability of the membranes and cell walls of these organisms means that the organisms cannot grow below temperatures at which conventional microorganisms would quickly die. The presence of pentacyclic rings in the biphytanyl chains (Fig. 2d) ensures that the fluidity of the membranes containing these lipids remains fairly constant as the temperature is increased above 80 °C. Many of these organisms have been isolated from deep-sea thermal vents,

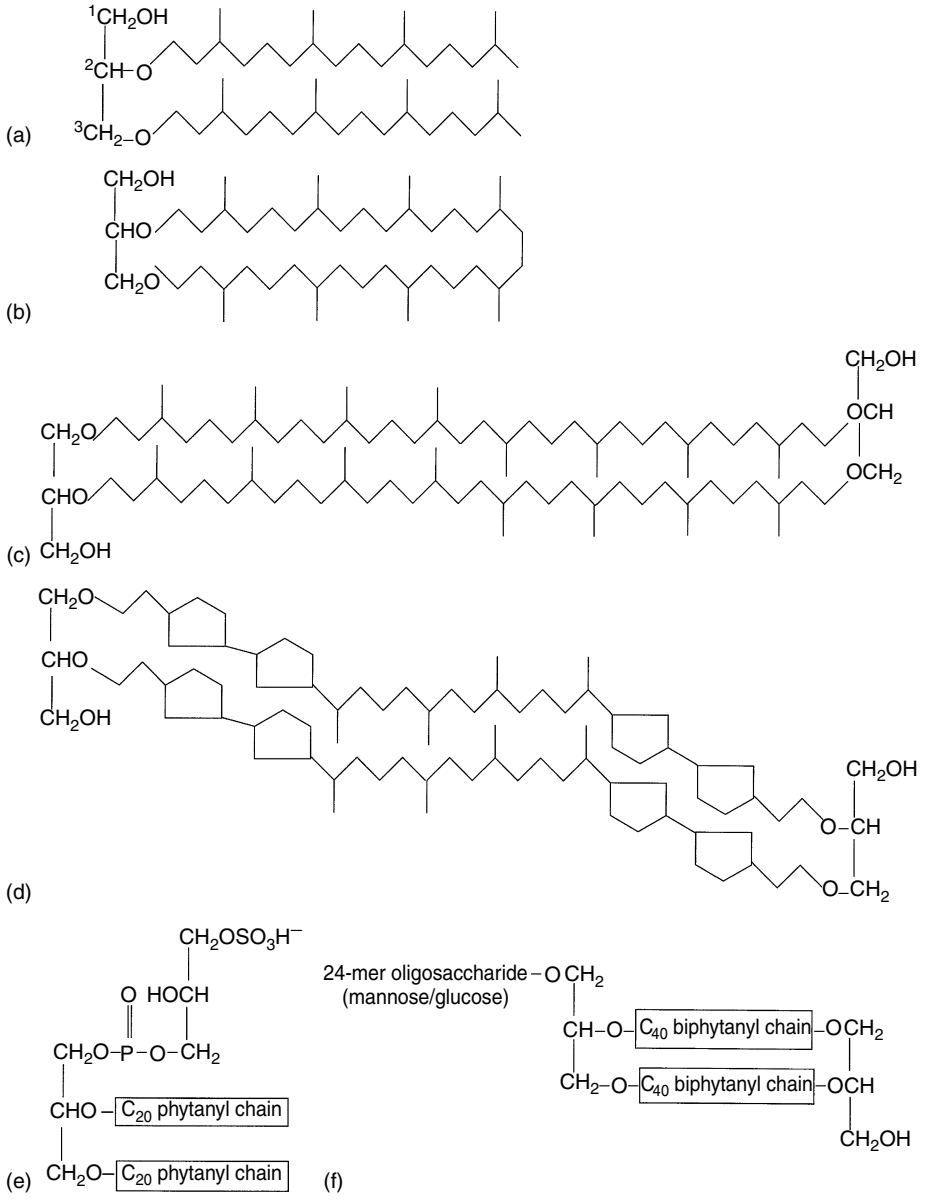

Fig. 2 Isoprenoid lipids of *Archaea:* (a) 2,3-di-*O*-phytanyl*sn*glycerol (archaeol), (b) 2,3-di-*O*-biphytanyl-*sn*-glycerol, (c) glycerol-dialkylglycerol tetraether (caldarchaeol), (d) tetracyclized glycerol dialkylnonitol tetraether (cyclized nonitolcaldarchaeol), (e) phosphoglycerolsulfate dialkylglycerol diether, (f) lipoglycan from *Thermoplasma* mannosyl-glucosyl oligosaccharide of (c).

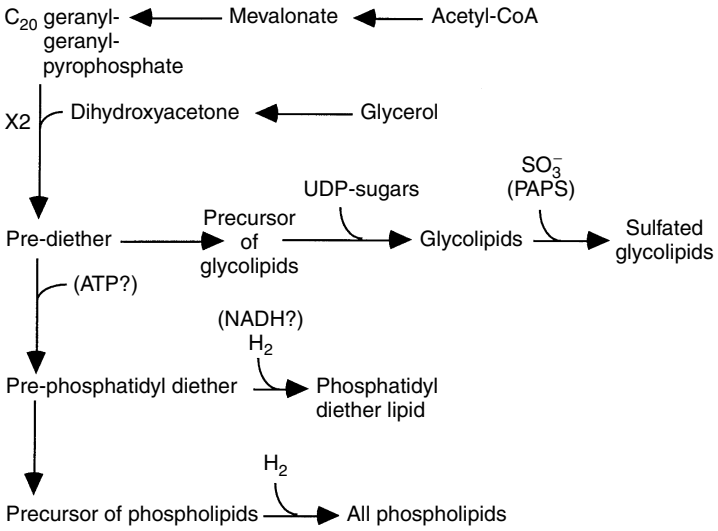

Fig. 3 Proposed pathways for the biosynthesis of the archaeol-containing phospho- and glycolipids in the extreme halophilic *Archaea*. (Adapted from the work of Morris Kates, University of Ottawa, Canada.)

demonstrating that their tolerance to temperatures in excess of 110 °C must be excellent.

Since the taxonomy of *Archaea* is still very much in its infancy, there is a considerable amount of work to be carried out on the structures of many of these organisms. Undoubtedly, some very complex lipids and lipid-containing molecules will be found in the next few years, and these will add to the bewildering array of the di- and tetraether lipids that have already been described.

3 Bacteria

''*Bacteria*'' is the term now applied to all bacteria except those now within the *Archaea*. It, therefore, comprises the bulk of ''conventional'' bacteria that were originally classified as the *Eubacteria*. These organisms synthesize ester-based lipids, usually based on glycerol, from fatty acids that are synthesized via the acetyl-malonyl pathway (see Fig. 1). In most cases, the resultant lipids are used as structural and functional entities in bacteria, being the component of the main phospholipid membranes of the cell. Also, however, they are used in conjunction with polysaccharides and peptides in the construction of the cell wall and other parts of the cell envelope. Bacteria are divided into two major groups, the gram-positive and the gram-negative organisms, reflecting differences in their cell wall structures. The former have a peptide-glycan outer shell acting as the wall, which is then anchored to the inner phospholipid bilayer membrane via lipoteichoic acids (**VII**). In gram-negative bacteria, there is an outer membrane, beyond the peptidoglycan layer, that is a matrix of phospholipids, complex lipopolysaccharides in which the porin uptake proteins are anchored. Lipoproteins are then used to link the outer membrane

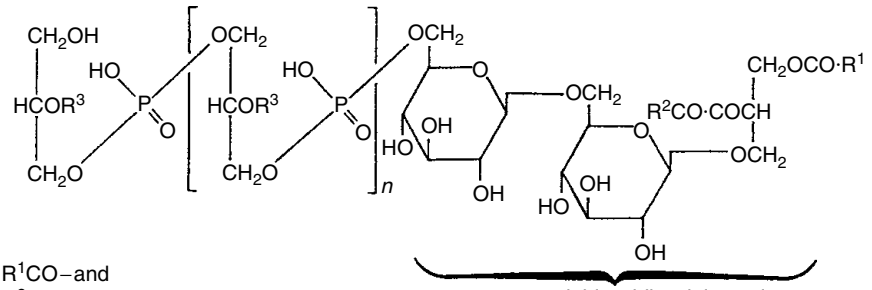
to the peptidoglycan layer that abuts the inner membrane. Most of the phospholipids are conventional diacylphosphoglycero derivatives (**II**) that are found in all living cells. There are, though, some variations in that ethanolamine, monomethyl-, and dimethylethanolamine may be used instead of choline (= trimethylethanolamine) as the polar basic group attached to the phospho group. Bacteria, apart from the mycobacteria, do not synthesize significant amounts of triacylglycerols (**I**).

The genetics of bacterial lipid metabolism are under active investigation by several major groups worldwide; the group led by John E. Cronan, Jr. (Urbana, IL) is particularly active in this respect.

3.1 Unsaturated Fatty Acids

In many bacteria, unsaturated fatty acids are synthesized by a so-called anaerobic pathway that is not found in other microorganisms. This pathway (Fig. 4) has been mainly studied in *E. coli*. It involves a modification of the existing fatty acid synthetase system (see Fig. 1) where, at the C_{10} level, there occurs an alternative dehydratase enzyme that forms 3*(Z)*-decenoate instead of the 2*(E)*-decenoate. (These terms replace the older descriptors of cis-β, γ-and *trans*-$\alpha\beta$-decenoates, respectively.) The latter intermediate is reduced and leads, via the continuation of fatty acid synthesis, to palmitoyl- and stearoyl-ACP (where ACP is a separable acyl carrier protein in *E. coli* having relative molecular mass of 8847). The 10 : 1 (*Z*3) intermediate cannot be reduced and is thus successively elongated so that the double bond remains in the molecule and, as it is elongated, the position of the double bond advances down the chain: 10 : 1 (*Z*3) → 12 : 1 (*Z*5) → 14 : 1 (*Z*7) → 16 : 1 (*Z*9) → 18 : 1 (*Z*11), which is *cis* (or *Z*)-vaccenic acid. This latter product is thus distinct from oleic acid, 18 : 1 (*Z*9), found in some bacteria and in all yeasts and molds. The presence of *cis*-vaccenic acid in extracted microbial lipids can be clearly distinguished from oleic acid by good gas chromatographic procedures, especially those using capillary gas chromatography.

The final elongation reaction of the "anaerobic" route is temperature sensitive. The enzyme that condenses 16 : 1 (*Z*9)-ACP (palmitoleoyl-ACP) with malonyl-ACP has a higher rate of reaction at lower temperatures than at



$R^1CO-$and

VII

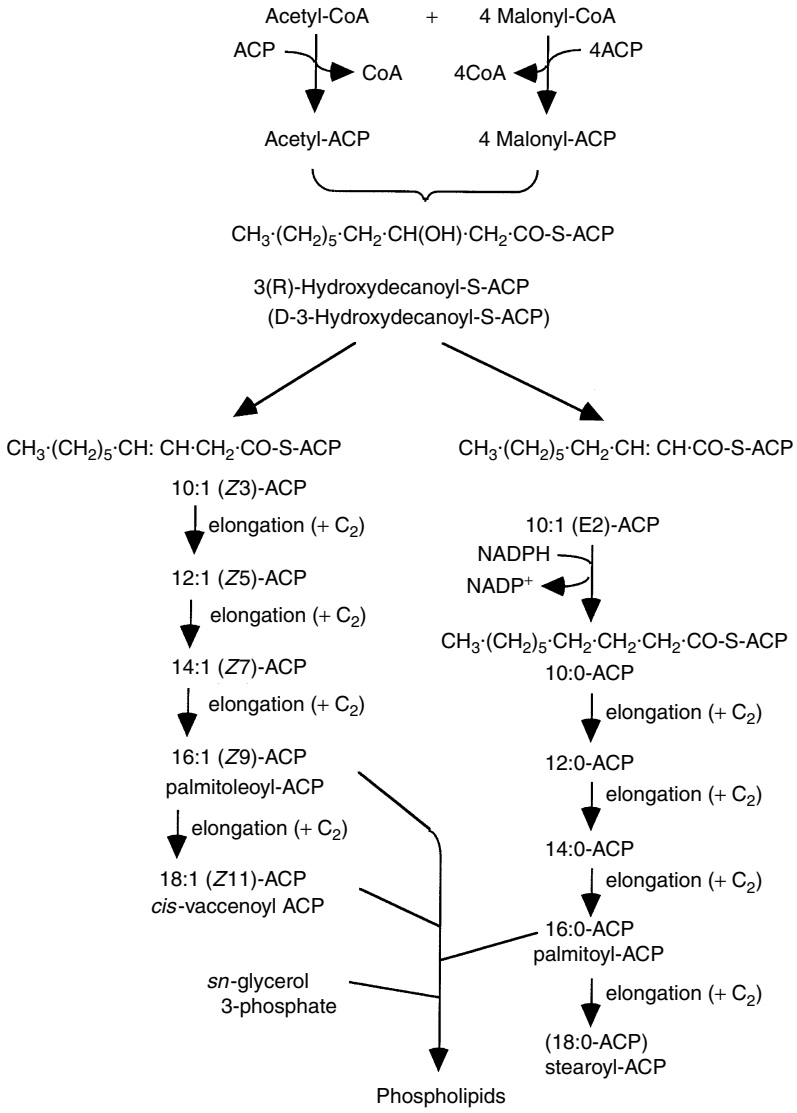

Fig. 4 Biosynthesis of saturated and unsaturated fatty acids by the fatty acid synthetase of *E. coli*. The conventional cyclic pathway of fatty acid biosynthesis condenses acetyl-ACP and malonyl-ACP in a succession of reactions leading to the formation of 3(*R*)-hydroxydecanoyl-*S*-ACP. This can either continue through the cyclic sequence to give the series of saturated fatty acids (right-hand side) or be dehydrated to give a fatty acid with the double bond now in a different position but also of a different isomeric configuration. Since this intermediate, the 3(*Z*)-decenoyl-ACP, now cannot participate in the reductive reaction, the double bond remains as the acyl chain continues to undergo further condensation reactions in the fatty acid synthetase cycle. The final conversion of 16 : 1 (*Z*9)-ACP to 18 : 1 (*Z*11)-ACP is a temperature-controlled reaction in that at low temperatures the condensing enzyme has a higher relative rate of reaction than at higher temperatures (see text).

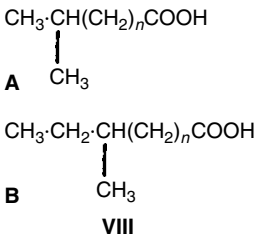
higher ones. Consequently, at low growth temperatures, more 18:1-ACP is formed than at higher temperatures, and it competes with palmitoyl-ACP for incorporation into phospholipids (see Fig. 4) and results in the formation of a higher proportion of diunsaturated acylphospholipids. This, in turn, ensures a lower temperature for the liquid phase transition of the membrane lipids. This temperature sensitivity of unsaturated fatty acid biosynthesis allows *E. coli* and other bacteria to adapt and to survive at low temperatures by modifying the fatty acyl constituents of the membrane phospholipids, ensuring that they remain as fluid as possible at lower temperatures.

3.2
Polyunsaturated Fatty Acids

Although the vast majority of bacteria do not synthesize polyunsaturated fatty acids because of the lack of specific desaturase enzymes, mycobacteria do synthesize fatty acids with multiple double bonds: for example, phleic acid is a 36 : 5 (4, 8, 12, 16, 20) fatty acid found in *Mycobacterium phlei* and *Mycobacterium smegmatis*. However, the double bonds are not of the methylene-interrupted type as found elsewhere. Such fatty acids, though, have been recognized in a number of bacteria recovered from fish intestines and include eicosapentaenoic acid, 20 : 5 (n-3), and docosahexaenoic acid, 22 : 6 (n-3). Although some interest has been indicated in these bacteria as potential sources of these very long-chain polyunsaturated fatty acids, better sources are various fungi and marine algae (see Sects. 5.3 and 6.2). The bacteria, however, could be useful providers of the genes needed to clone into plants if genetically modified plants are to be created that can synthesize these nutritionally desirable fatty acids.

3.3
Branched Chain Fatty Acids

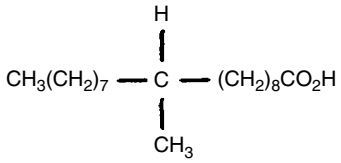
Branched chain fatty acids with a methyl group at the penultimate or antepenultimate carbon atom (see **VIIIA** and **B**) are synthesized by both gram-positive and gram-negative bacteria. The principal genera among the former group that produce branched chain fatty acids are *Bacillus, Clostridium, Listeria, Micrococcus, Sarcina,* and *Staphylococcus*; of the gram-negatives, *Flavobacterium, Bacteroides, Legionella, Vibrio,* and *Desulphovibrio* are the principal genera, though some species of *Pseudomonas* and *Xanthomonas* also contain these acids. The branched chain fatty acids are synthesized from the derivatives arising from the branched chain amino acids: leucine (or valine) for the iso-fatty acids and isoleucine for the anteiso-fatty acids (see **VIIIA** and **B**).



VIII

Fatty acids with a methyl branch in the middle of the chain are also known. The best-known example of this is tuberculostearic acid, 10-methyloctadecanoate (**IX**), which was originally isolated from the tubercle bacillus *Mycobacterium tuberculosis* but has now been found in more than 20 difference species and strains of *Mycobacterium* besides also occurring in a number of other actinomycetes.

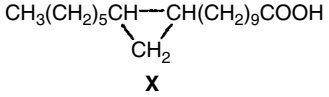
A number of other methyl-branched fatty acids also occur in mycobacteria, including small amounts of the iso- and anteiso-fatty acids, as well as multi-methyl-branched fatty acids of which the C_{32} mycocerosic acid 2,4,6,8-tetramethyloctadecanoate is but one of several complex branched chain fatty acids found in this genera (see also Sect. 3.6, Mycolic Acids).



IX

3.4
Cyclopropane Fatty Acids

Fatty acids that contain a cyclopropane ring are fairly common in bacterial lipids. The most widely distributed example is lactobacillic acid, Z-11, 12-methyleneoctadecanoic acid (**X**), abbreviated as 19:0 cy. This, as the name would suggest, was originally isolated from *Lactobacillus* spp. but is recognized now in many organisms including *E. coli*, most *Pseudomonas* spp., and some *Rhizobium* and *Clostridium* spp. The corresponding 17 : 0 cy fatty acid also occurs. The presence of these acids can be regarded as indicative of a unique bacterial lipid because they do not occur in eukaryotic microorganisms: a related fatty acid, sterculic acid (an unsaturated 19 : 1 cy fatty acid), though, does occur in some plant lipids.



X

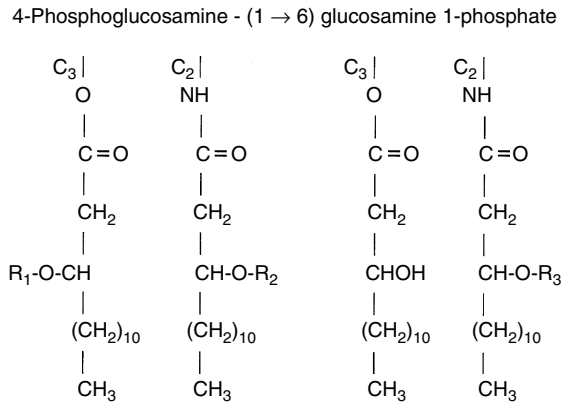
3.5
Hydroxy Fatty Acids

Hydroxy fatty acids are constituents of lipopolysaccharides of the cell envelope of the gram-negative bacteria and have been found in most species that have been studied. 3-Hydroxyalkanoic acids, ranging from C_{11} to C_{21}, have been identified in *E. coli* and species of *Salmonella, Klebsiella, Yersinia, Vibrio, Pseudomonas, Xanthomonas*, and *Rhizobium*. 2-Hydroxy fatty acids also occur to a lesser extent; however, the steric configuration of this hydroxy fatty acid is the *S* (or *L*) form and is thus opposite to the *R* (or *D*) form of the 3-hydroxy fatty acid. This probably indicates separate biosynthetic origins for the two fatty acids. 3-Hydroxy iso-fatty acids may be detected in some species as minor constituents.

The arrangement of the 3-hydroxy fatty acids (of which 3-hydroxy tetradecanoate is the most abundant type) is shown in Fig. 5 as part of the lipid A structure of some enterobacteria. Lipid A is the anchor region of the complex lipopolysaccharide structure in the outer membrane of these organisms. The fatty acids attached to the diglucosamine will then adjoin the periplasmic space.

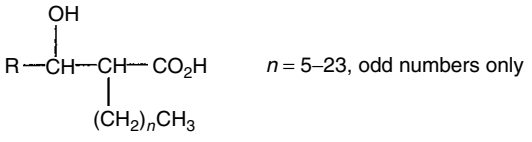
3.6
Mycolic Acids

Very long chain, hydroxylated, branched chain fatty acids occur in bacteria belonging to the *Mycobacterium, Nocardia, Corynebacterium* group, *Rhodococcus*, and related groups of bacteria. The basic structure is that of a 2-alkyl, 3-hydroxy fatty acid (**XI**). The alkyl side chain may be up to 24 carbon atoms long (as occurs in *M. tuberculosis*); it is shorter in other mycobacteria. In *Corynebacterium* spp. it is only six carbons long. The long-chain group attached

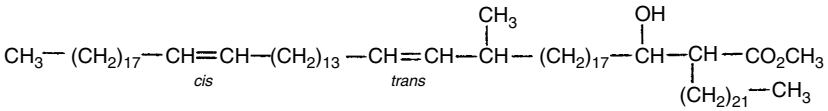


Lipid A	R_1	R_2	R_3
Salmonella minnesota	14:0 and 2-HO-14:0	12:0	16:0
Escherichia coli	14:0	12:0	H
Proteus mirabilis	14:0	14:0	H and 16:0

Fig. 5 Structure of lipid A in three enterobacteria.

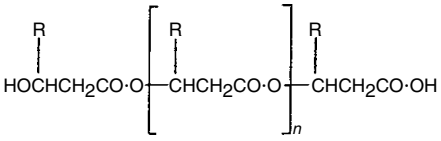


XI



XII

at C-3 of the mycolic acid is up to 61 carbon atoms, making some of the mycolic acids the largest unsubstituted lipids that occur in any organism. A typical mycolic acid, as found in *M. smegmatis* as its methyl ester ($C_{80}H_{156}O_3$), is shown in structure **XII**.



XIII

3.7 Polyesters

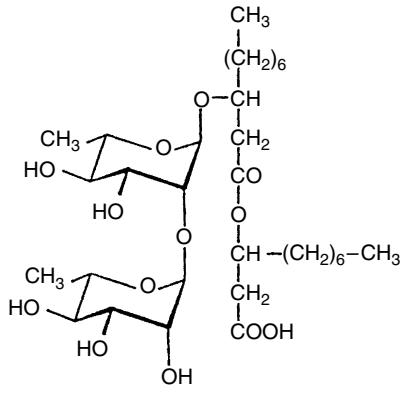
Bacteria, apart from some exceptions in the *Mycobacterium* genus, do not synthesize triacylglycerols, which are the usual storage lipid of eukaryotic microorganisms (see Sects. 4.1 and 5.3). Lipid storage, nevertheless, still occurs

in bacteria by the biosynthesis of high molecular weight polyesters of β-hydroxybutyrate (PHB) or polyesters of β-hydroxyalkanoate (PHA). Poly-β-hydroxybutyrate (R = $-CH_3$ in **XIII**), which is the *D* (or *R*) isomer, is synthesized by a large number of bacteria; species of *Alcaligenes, Azotobacter, Bacillus, Nocardia, Pseudomonas, Rhizobium, Rhodococcus,* and *Zoogloea*, plus *E. coli*, have been investigated in numerous laboratories. In some bacteria, the more ubiquitous PHB is replaced by a poly-β-hydroxyalkanoate (PHA) in which the side chain (R in **XIII**) may be up to 12 carbon atoms long. PHB has also been found in some fungi.

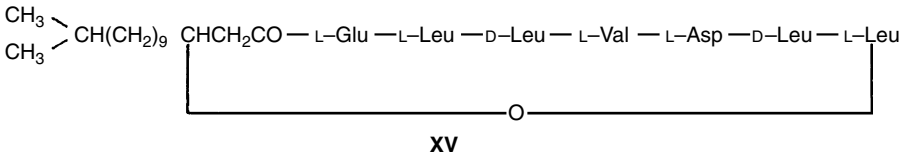
PHA, which can reach up to 80% of the biomass of *Alcaligenes eutrophus*, and also in a recombinant strain of *E. coli*, can attain molecular sizes of over 1 million Daltons and, moreover, be produced by the bacteria with a combination of side chains (see **XIII**) which then endows the resultant biopolymer with properties that can be designed with a particular function in mind. Nevertheless, in spite of all these advantages, including biodegradability, neither PHB nor PHA has achieved commercial production mainly because the costs involved are about ten times those of producing polyethylene and related chemical polymers.

Some hope for commercial production was considered to be by way of introducing the requisite three key genes for PHB synthesis (see Fig. 6) into a plant such as rapeseed, sunflower, or soybean. Unfortunately, yields of the biopolymer were not as good as in the bacteria and costs of production were again found to be higher than costs of producing conventional plastics. A limited amount of commercial interest only remains in these unique bacterial polymers once considered as the "green" alternative to petrochemically produced plastics.

Since the pathway for PHB biosynthesis requires only three new enzymes (see



XIV



XV

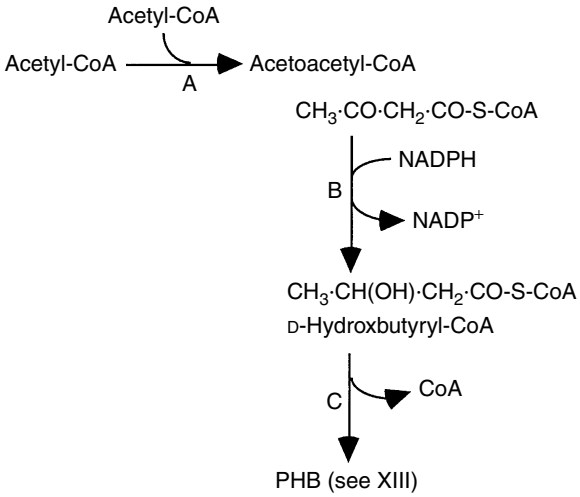


Fig. 6 Biosynthesis of poly-β-hydroxybutyrate in bacteria. Enzymes are 3-ketothiolase (A), acetoacetyl-CoA reductase (B), and PHB synthetase (C).

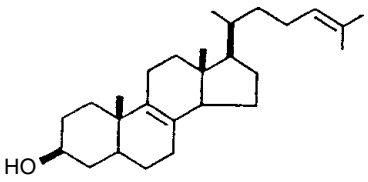
Fig. 6), prospects of cloning the corresponding three genes into plants has been under consideration. All three genes have been isolated and sequenced. Plants that normally synthesize considerable amounts of oil, thereby already having good supplies of acetyl-CoA, are the obvious recipients of the gene transfer: rapeseed, sunflower, and soybean are all currently receiving attention. However, the cost of producing these materials, even using genetically modified plants, appears to be more than the market is willing to pay for biodegradable plastics.

3.8 Biosurfactant Lipids

Bacteria produce a number of biosurfactants of diverse chemical structures that have the ability to form stable emulsions of oil and water mixtures. Most of the biosurfactants owe their properties to being glycolipids (see **XIV**); that is, they possess both water-soluble and oil-soluble components. Some, however, are lipopeptides (see **XV**). Highest concentrations of these compounds are produced during bacterial growth on oils, either petroleum or plant in origin. Several of these biosurfactants are produced commercially or are undergoing industrial investigation. They include emulsan, which is produced by *Acinecobacter calcoaceticus* RAG-1 and is a polyanionoic, amphipathic, heterolipopolysaccharide of high molecular weight (1 MDa), rhamnolipids (**XIV**) produced by *Pseudomonas* spp., and surfactin (**XV**) produced by *Bacillus subilis*. Other biosurfactants of commercial interest are produced by yeasts and molds (see Sects. 4.4 and 5.4).



XVI

4
Yeasts

4.1
Fatty Acids and Fatty Acyl Lipids

Yeasts are eukaryotic, unicellular fungi that do not form a mycelium and, thus, are differentiated from the filamentous fungi. There are over 600 identified species of yeasts. Yeasts, like all eukaryotic organisms, synthesize their fatty acids via the acetate–malonate route (Fig. 1) and possess specific desaturases for the conversion of saturated fatty acids to unsaturated ones. Most fatty acids are 16 to 18 carbon atoms in length, though small amounts of fatty acids as long as 28 or 30 carbons can be discerned by careful analysis of some species.

Yeasts tend to have a much more limited range of fatty acids than molds: oleic (18 : 1), palmitic (16 : 0), linoleic (18 : 2), and palmitoleic (16 : 1) acids usually account for more than 90% of the total fatty acids. Typical fatty acid profiles of yeasts are shown in Table 1.

Tab. 1 Typical fatty acid profiles of some selected yeasts.

[a] Considered to be oleaginous species with oil contents >25% of cell dry weight.
[b] Now reclassified as *Cryptococcus curvatus*.

Fatty acid profiles of all the major genera and of the key species within each genus now have been published. The most systematic and extensive survey was conducted by Lodewyk Kock and his associates in Bloemfontein, South Africa. Although most yeasts (see Table 1) synthesize di- and polyunsaturated fatty acids (18 : 2 and 18 : 3), *Saccharomyces cerevisiae* (baker's and brewer's yeast) does not synthesize unsaturated fatty acids beyond oleic acid (18 : 1). Reports of the occurrence of 18 : 2 and 18 : 3 in *S. cerevisiae* continue to be made, though their presence is attributable to the yeast being grown on a culture medium that contains animal- or plant-derived material bearing traces of these acids. Other yeasts, though, synthesize both 18 : 2 and 18 : 3, which is the α-isomer [i.e. 18 : 3 (9, 12, 15)].

Fatty acids are incorporated into a range of acylglycerophospholipids (**II**) of which phosphatidylcholine, -serine, -ethanolamine, and -inositol are the major ones; diphosphatidylglycerol (cardiolipin) is also common. Many yeasts also synthesize small amounts of sphingolipids (whose function is largely unknown). Unlike bacteria, all yeasts synthesize some triacylglycerols (**I**) along with the functional phospholipids. Triacylglycerols function as a reserve storage product; in some yeasts (about 25 or so species), the amount of triacylglycerol that is stored can be up to 80% of the cell volume. Such yeasts are known as oleaginous species and have been examined as potential sources of oils because the extracted triacylglycerol is similar in composition to several of the commercially produced plant oils.

4.2 Single Cell Oils (SCO)

Microbial lipids that have been considered as sources of edible oils are referred to as *single cell oils* (SCO), as an equivalent term to *single cell proteins*, which describes microorganisms as potential sources of protein or food. In view of the high costs of biotechnological production of such oils, commercial interests have centered on the highest valued oils. For yeasts, this focus has been in the production of a substitute for cocoa butter. (With molds, commercial interest has been directed mainly on the polyunsaturated fatty acids: see Sect. 5.) The main yeast to have been examined was *Candida curvata* (also known as *Apiotrichum curvatum*), now renamed *Cryptococcus curvatus*. To replicate the fatty acid composition of cocoa butter, it was necessary to delete the Δ9-desaturase gene converting stearic acid to oleic acid, thus causing the accumulation of stearic acid up to 40% in the yeast oil (see Table 2). The high content (35%) of stearic acid in cocoa butter gives the product its characteristic hardness at ambient temperatures, with a sharp transition to the molten state at 30 to 32 °C.

The genetic modification of *Candida curvata* was carried out by Henk Smit and colleagues at the Free University of Amsterdam. The yeast has also been explored commercially in New Zealand by Julian Davies (Industrial Research Ltd., formerly the Department of Scientific and Industrial Research of the New Zealand government) using as a low cost substrate the waste lactose from whey arising during cheese manufacture. Even with such a cheap feedstock, however, the biotechnological route has not proved to be commercially competitive against cocoa butter or equivalent fats that are produced from palm oil by fractional recrystallization. Interest in this particular SCO has therefore ceased.

Tab. 2 Cocoa butter fatty acids and the fatty acyl composition of yeast triacylglycerols[a].

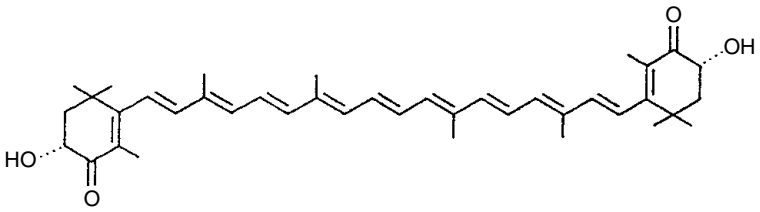
[b] Wild type grown (in New Zealand) on whey lactose.
[c] Grown with 0.2 g oleic acid L^{-1}.

4.3 Biochemistry of Oleaginicity

The biochemical reason for the relatively sparse distribution of oleaginicity among yeasts (of 600 plus species, only some 25 or so yeasts are known that accumulate >25% lipid) has been identified as the key presence of ATP: citrate lyase (ACL) in the oleaginous species (see Fig. 7). In this scheme, citric acid, which is produced within the mitochondrion, is not further metabolized through the reactions of the tricarboxylic acid cycle because, under the conditions that lead to the accumulation of lipid (exhaustion of N from the culture medium), isocitrate cannot be converted to α-ketoglutarate. This conversion is prevented because adenosine monophosphate (AMP) reaches such a low intracellular concentration under these conditions that isocitrate dehydrogenase, which specifically requires AMP for activity, cannot become fully operational. Thus, when cells have exhausted their supply of N in the medium, the concentration of AMP falls, preventing citrate metabolism; then, provided a supply of carbon (e.g. glucose) is still available, the cells begin to accumulate citrate, which exits the mitochondrion and is cleaved by ACL to yield acetyl–CoA units. The other product from the ACL reaction is oxaloacetate, which is recycled to pyruvate via malic acid; which is decarboxylated to pyruvate by malic enzyme and simultaneously produces the NADPH that is needed for fatty acid biosynthesis. Although all oleaginous yeasts possess ACL, not all possess malic enzyme; at least some species, therefore, must have available an alternative means of generating NADPH and recycling the oxaloacetate. The underlying biochemistry of oleaginicity in yeasts and molds has been largely worked out in the author's laboratory.

The genetics of fatty acid and phospholipid biosynthesis has been examined principally in *S. cerevisiae*, which is not



XVII

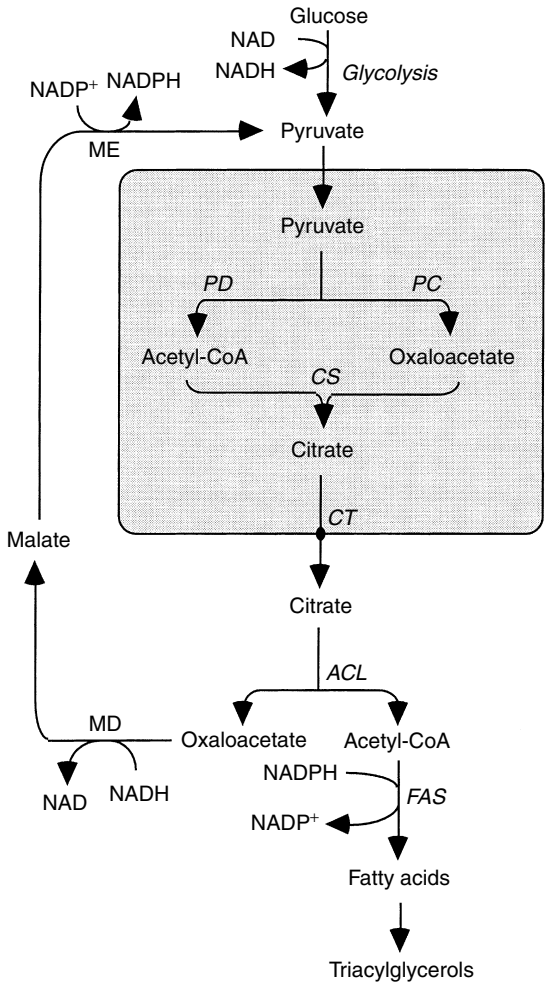


Fig. 7 Mechanism of acetyl–CoA production in oleaginous yeasts and molds leading to the accumulation of single cell oils (triacylglycerols). The metabolism of glucose to pyruvate occurs by *glycolysis* in the cytoplasm; pyruvate is transported into the mitochondrion (shaded box) and is converted to acetyl–CoA and oxaloacetate (by pyruvate dehydrogenase, *PD*, and pyruvate carboxylase, *PC*, respectively), which are synthesized into citrate via citrate synthetase (*CS*). Citrate is translocated via citrate translocase (*CT*) out of the mitochondrion, to be cleaved by ATP: citrate lyase (*ACL*). The acetyl–CoA then is used for fatty acid synthesis (*FAS* = fatty acid synthetase) and oxaloacetate is converted by malate dehydrogenase (*MD*) and malic enzyme (*ME*) back to pyruvate. Malate dehydrogenase uses NADH, which will be provided by the key reactions of glycolysis: *ME* generates the NADPH needed for fatty acid biosynthesis.

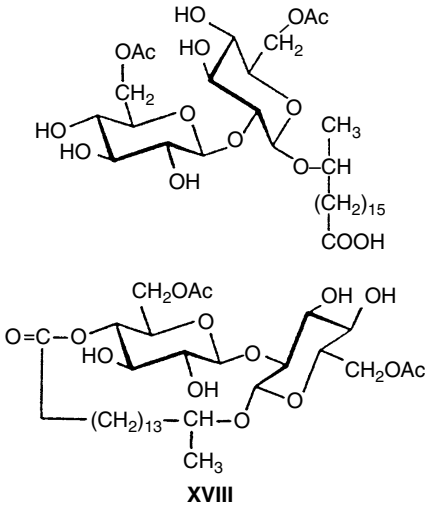
an oleaginous species and does not contain ACL activity. Leading investigators of these processes are Susan A. Henry at Cornell University and George M. Carman at Rutgers University, in New Jersey.

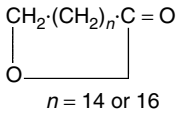
4.4 Other Lipids

Yeasts synthesize varying amounts of terpenoid lipids. Sterols, mainly ergosterol (**III**) and zymosterol (**XVI**), occur in all yeasts but usually at no more than 1% of the cell dry weight. However, in some species of *S. cerevisiae*, ergosterol has been reported up to 10%, and, in one case, up to 20% of the cell dry weight. However, this sterol is not of commercial importance.



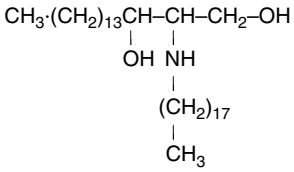
XVIII

Many yeasts do not synthesize carotenoids lipids. These include, obviously, the *Candida* (from *candidus*, Latin for white) yeasts. Various carotenoids, though, are produced in some abundance by the pink and red yeasts: principally, *Sporobolomyces, Rhodotorula/Rhodosporidium*, and *Phaffia*. The carotenoid produced by *Phaffia rhodozyma* is astaxanthin (**XVII**), which is now produced commercially as a supplement to fish feed, being a source of red pigmentation for the coloration of salmonid fish.



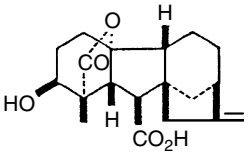
$n = 14$ or 16

XIX



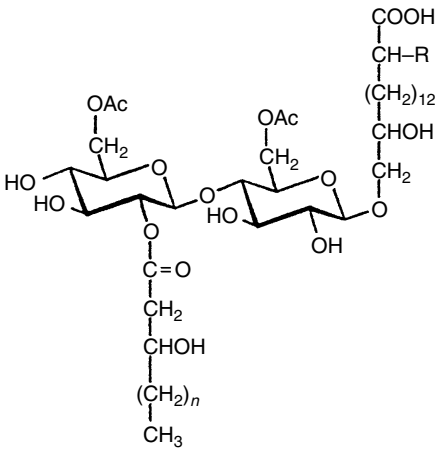
XX

Yeasts, like bacteria, also produce a number of biosurfactants when grown in hydrocarbons or other water-insoluble substrates. The most widely known of these are the sophorolipids (**XVIII**) produced by *Candida bombicola* and related species. Yields may exceed 100 g L^{-1}, but commercial uptake has been very limited because the sophorolipids, though efficacious as emulsificants, have little advantage over the much cheaper, chemically produced surfactants. The key component fatty acyl group of the sophorolipid from *C. bombicola* is a ω- or ω-1-hydroxy fatty acid, which may be lactonized into a macrocyclic lactone (**XIX**) that has some potential use as perfumery intermediate.



XXI

Although ceramide lipids are usually only minor components of microbial lipids, *N*-stearolyphytosphingosine (**XX**) is now being produced commercially using *Pichia* (formerly *Hansenula*) *ciferri*. The ceramide, after purification, is incorporated into various preparations being used in the cosmetics industry, and is also of some potential in the health care industry for treatment of various skin disorders.



XXII

5 Molds

5.1 Fatty Acids

Some 60 000 individual species of filamentous fungi are known. These microorganisms, which are also referred to as *molds*, synthesize a range of fatty acids, from 12 to 24 carbon atoms in chain length and include polyunsaturated fatty acids up to 22 : 6 (docosahexaenoic acid). Although no systematic survey of mold lipids has been carried out, analysis of most of the easily cultivatable genera has been accomplished. Table 3 gives some of the different ranges of fatty acids that are found. Very little work has been carried out in the genetics of molecular biology of fungal lipids. In a number of species, there may be extensive accumulation of triacylglycerols as storage reserves; oil contents exceeding 70% have been recorded in several instances. The biochemistry of lipid accumulation and of biosynthesis appears to be similar to those processes elucidated with yeasts.

Besides the conventional straight chain fatty acids, some species of the order of phycomycetes produce iso- and anteiso-fatty acids (**VIIIA, B**). Ricinoleic acid, 15-hydroxyoleic acid, which is the principal fatty acid found in castor oil, occurs in *Claviceps* species.

5.2 Polyunsaturated Fatty Acids

One of the few differences in fatty acid composition between representatives of the three main orders of molds – the phycomycetes (or lower fungi), the ascomycetes (also known as the fungi imperfecti), and the higher fungi or basidiomycetes – is that the phycomycetes synthesize unsaturated fatty acids of the n-6 series. The ascomycetes and basidiomycetes fungi, in contrast, synthesize n-3 fatty acids. The biosynthetic route to these two series of fatty acids is shown in Fig. 8. These two pathways are similar to those that occur elsewhere: the n-6 route is an ''animal''-only route, and the n-3 route is found in plants. Uniquely, some fungi are able to convert arachidonic acid as a member of the n-6 series to eicosapentaenoic acid, which belongs to the n-3 series, by the action of a Δ17-desaturase that is not found in other organisms. The ability of fungi to synthesize fatty acids longer than C_{18} is very restricted, however,

Tab. 3 Typical fatty acid profiles of some selected filamentous fungi.

[a] γ-linolenic acid, 18 : 3 (6, 9, 12).

and tends to occur to any appreciable extent only in some representatives of the phycomycetes fungi.

5.3 Single Cell Oils

Commercial interest in fungal oils has centered on the species that produce an abundance of certain polyunsaturated fatty acids. Oils (triacylglycerols) containing such fatty acids are used as dietary supplements, and numerous claims are made for their efficiency in the treatment of disorders as varied as childhood eczema and premenstrual tension, and in the prevention of heart disease. The inclusion of particular polyunsaturated fatty acids into infant milk formulations has also been advocated because these acids, which occur

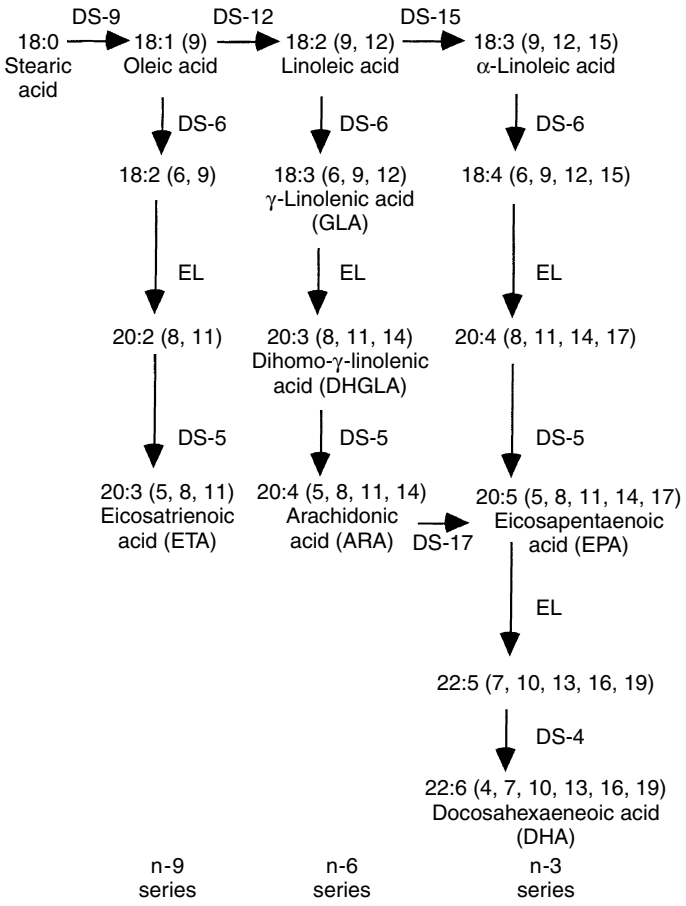

Fig. 8 Pathways of polysaturated fatty acid biosynthesis in fungi: DS-N, desaturase operating at *N*th carbon atom in chain; EL, elongase (acetyl–CoA dependent). The notations n-9, n-6, and n-3 indicate the position of the last double bond that is furthest away from the respective carboxylic acid group.

in human milk, are completely lacking in cow's milk.

Of particular interest are fungi that produce γ-linolenic acid (GLA), 18 : 3 (6, 9, 12), which is currently available only in the seed oil of the evening primrose (*Oenothera bienesis*), borage (*Borago officinalis*), and, as a mixture with the α-isomer, 18 : 3 (9, 12, 15), in *Ribes* spp. (blackcurrant, redcurrant, and so on). The high cost of these plant oils (between $10 and $15 per kg, though prices are very variable and have been both lower and higher in recent years) has made the biotechnological route using species of *Mucor, Mortierella*, and *Rhizobium* particularly attractive. Commercial processes using species of the former two genera were developed in the 1980s and ran into the 1990s, though, neither operates today (2004). In the United Kingdom, a process

was operated by J. & E. Sturge Ltd, Yorkshire, using *Mucor circinelloides* grown in fermenters of up to 220 m^3 with the oil being sold under the trade name of Oil of Javanicus. This became the world's first commercially produced single cell oil.

The oil had the highest possible purity and satisfied all regulatory guidelines for its quality. In Japan, a similar process was developed later by Idemitsu Kosan Co. Ltd, Tokyo, using *Mortierella isabellina*. Production of both oils ceased primarily because of the cheaper plant oils that became available, especially borage oil (also known as starflower oil) which had a superior content of GLA over the mold oils (see Table 4 for comparisons between the fungal oils and plant oils containing GLA).

The market for oils rich in GLA now appears to be met by borage and evening primrose oils and both have developed their own niche positions making it difficult for alternative sources of GLA to displace them. This includes the possible production of GLA using a genetically modified plant, such as sunflower, in which the gene coding for the D6-desaturase, that converts the existing linoleic acid (18 : 2) into GLA (see Fig. 8), has been inserted into the plant. The reluctance of the commercial owners of this technology to develop the GM crop for GLA oil production is perhaps understandable because of the current political pressures (especially in the United Kingdom and other European countries) against such technology and the advent of the cheaper borage oil.

One single cell oil process using a mold continues to be of increasing commercial importance and this is for the production of an oil rich in arachidonic acid (ARA), 20 : 4 (n-6) – see Fig. 8. This polyunsaturated fatty acid is now recommended for inclusion in infant formulae along with docosahexaenoic acid (DHA) 22 : 6 (n-3) whose production as another single cell oil is described in Sect. 6.2. The functional roles of ARA and DHA are considered to be in the development of retinal and neural membrane lipids and are thought to be of diminished availability if babies are not being fed upon mother's milk.

[a] Production organism used by J. & E. Sturge Ltd., UK
[b] Production organism used by Idemitzu Ltd., Japan; ND, not disclosed but probably about 45–50%.
[c] Also contains 20 : 1 (4.5%), 22 : 1 (2.5%), and 24 : 0 (1.5%); 22 : 1 is erucic acid.

Supplementation of infant formulae by both these fatty acids has now been recommended in over 60 countries, including the United States and most European countries. Infants receiving these supplements are considered to have improved development of memory and of eyesight.

The organism of choice for ARA production is *Mortierella alpina*. The mold is grown in large-scale fermenters and produces an oil content of about 40% of its biomass with ARA at about 45% of the total fatty acids. Various descriptions of this process have been given. The final oil is diluted with some sunflower oil in order to bring the ARA content down to a standard level of 40%. The oil itself has passed every stringent test and is regarded as entirely safe for ingestion by infants as well as adults, including pregnant females. A profile of the fatty acids of this oil is shown in Table 5.

5.4 Other Lipids

Molds, like yeasts, contain a wide variety of lipids. Some of these lipids are associated with various aspects of fungal differentiation, and certain lipids are found only in association with fungal spores or with particular stages of fungal development. As an example of this, ricinoleic acid (15HO-18 : 1), is found in *Claviceps purpurea*, but only in association with the sclerotial stage of development of this fungus. No 15HO-18 : 1 is found when *C. purpurea* is grown in its mycelial form in submerged culture.

Sterols occur in all molds. Ergosterol (**III**) is the commonest one, but many others (>40) are known.

Carotenoids occur in about 60% of all fungi. β-Carotene (IV) is produced commercially using *Blakeslea trispora* and, though most processes have now ceased owing to the availability of cheaper, chemically produced material, at least one process still continues in eastern Europe.

The group of compounds known as the gibberellins are diterpenes and are biosynthetically derived from a common intermediate of the carotenoid pathway (geranyl geranylpyrophosphate). These are commercially produced as plant growth hormones using *Gibberella fujikuroi*, which

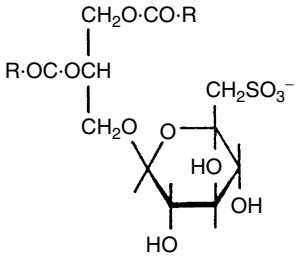
Note: ARASCO, DHASCO, and DHAGold are registered trade names of Martek Bioscience Corp., MD, United States of America. ARASCO and DHASCO are combined together at a 2 : 1 ratio and used for incorporation into infant formulae under the trade name of Formulaid.

is the telomorphic state of *Fusarium moniliforme*. The principal product is gibberellic acid (**XXI**), though some 80 different variations of this compound are known.



XXIII

A number of surfactants are also produced by fungi. Like those produced by other microorganisms, they are effective in creating stable oil–water mixtures. They may, therefore, be functionally useful to microorganisms that inhabit the phyllosphere and, as such, may improve attachment of the fungi (mycelial cells or spores) to plant leaves. A surfactant based on cellobiose from the maize rust fungus *Ustilago maydis* is known as ustilagic acid (**XXII**).

6
Unicellular Algae

The term ''algae'' encompasses 14 major groups or classes ranging from prokaryotic bacteria through the yellow, green, golden, and brown macroalgae, which includes both the seaweeds and diatoms. Most algae are photosynthetic organisms, though some may grow heterotrophically – that is, using fixed carbon compounds rather than CO_2, from which both carbon and energy may be obtained. When CO_2 is used as the carbon source, sunlight is then usually used, via photosynthesis, as the source of energy.

6.1
Cyanobacterial Lipids

The prokaryotic algae, or cyanobacteria, were originally referred to as the *blue-green algae*. The principal genera are *Anabena, Anacystis, Nostoc, Oscillatoria, Spirulina*, and *Synechococcus*. The lipids of these genera are diverse and, of course, include chlorophyll, which is an essential part of the photosynthetic apparatus. Whereas bacteriochlorophylls are found in the green and purple photosynthetic bacteria (*Rhodospirillaceae, Chromatiaceae*, and *Chlorobiaceae*), plant chlorophyll is found in the cyanobacteria. This then suggests that cyanobacteria are the ancestors of the chloroplasts of plants. The neutral lipids of cyanobacteria include many carotenoid pigments, hydrocarbons, hopanoids, quinones, and, in some species, poly-β-hydroxybutyrate (**XIII**). The principal polar lipids of the cyanobacteria are phosphatidylglycerol and sulfoquinovosyldiacylglycerol (**XXIII**), which are regarded as the sulfolipid characteristic of plants. The fatty acyl substituents of these lipids are ''plant-like'' rather than ''bacteria-like'' and include oleic acid (18 : 1), linoleic acid (18 : 2), and either γ- or α-linolenic acid (18 : 3), according to the genus. A number of conjugated lipids also occur that are associated with the cell envelope; these include lipopolysaccharides forming lipid A (see Fig. 5) as part of the cell envelope. The cyanobacterial cells are usually low in total lipid contents (<15%) and, because of the wide diversity of types, are not usually considered commercially exploitable, given the impracticality of purifying individual lipids. However, an exception may be possible

with *Spirulina*, which has been researched with some enthusiasm in Israel by Zvi Cohen and his colleagues, at the Ben Gurion University, in the Negev Desert.

Spirulina platensis and *Spirulina maxima* are multicellular, filamentous cyanobacteria that profusely colonize lakes in Africa and Mexico. They have been used as indigenous supplies of food and feed and are of some commercial interest because both have been known for some time to contain γ-linolenic acid. Although the algae grow well in outdoor lagoons in hot, sunny climates and can, indeed, produce in the extracted lipid a GLA content exceeding 20%, the distribution of GLA between neutral lipid (e.g. triacylglycerols), glycolipid, and phospholipid fractions is about 1 : 9 : 4. This, coupled with the low (<6%) content of lipid in the cells, probably makes it a commercially unattractive source of the fatty acid. With appropriate marketing, however, it could be used to boost the nutritional claims for whole-cell *spirulina* as a dietary supplement.

6.2 Eukaryotic Algae Lipids

6.2.1 Carotenoids

Of the nonfatty acyl lipids, carotenoids have been of some commercial interest. The production of β-carotene (**IV**) by *Dunaliella salina* has been investigated by a number of groups worldwide, with those in Israel, Western Australia, and California being particularly active. Commercialization of this process has now been developed in Western Australia by Aqua-Carotene Ltd., which uses outdoor cultivation ponds to produce the biomass.

Also of increasing commercial interest is another carotenoid, astaxanthin, which is used principally as a colorant for feeding farmed fish. This is produced by *Haematococcus pluvialis*, which can contain over 2% of its biomass as astaxanthin. It is grown in large-scale ponds and is sold as an alga meal by a number of companies. Chemically produced carotenoids, however, remain cheaper than the algal sources but do not have the benefit of being able to claim that they are ''natural'' ingredients. This is possibly not a deterrent when considering large-scale use where cost is the priority, though, legislation in individual countries may dictate otherwise.

6.2.2 Polyunsaturated Fatty Acids

Several commercial processes now exist for the production of the very long-chain fatty acid, docosahexaenoic acid, 22 : 6 n-3, (DHA). This fatty acid is now recommended for inclusion in infant formulae along with arachidonic acid, see Sect. 5.3. It is also recommended for dietary supplementation for adults, where it may offer protection against coronary heart diseases. It is preferred, in some cases, to fish oil which, though containing DHA, also contains eicosapentaenoic acid, 20 : 5 n-3, (EPA) and which may be contraindicated as it can interfere with the uptake and functional role of DHA. Fish oil is not allowed as a supplement for infant formulae in some countries, including the United States, because of its possible contamination with environmental toxins and heavy metals.

The main production organism for DHA is *Crypthecodium cohnii*, which is a unicellular, nonphotosynthetic dinoflagellate. It is grown in large-scale fermenters of up to 100 m^3. The principal company behind the development of the process and the marketing of the oil is Martek Biosciences Corp., Maryland, United States. The oil is known by the trade name of DHASCO and, when mixed with arachidonic acid for

incorporation into infant foods, is known as Formulaid. The fatty acid profile of the oil is shown in Table 5, where it can be seen that DHA is the sole polyunsaturated fatty acid thereby making the oil highly desirable as a source of this single PUFA.

Another related process for the production of DHA uses another marine organism known as *Schizochytrium*. The inclusion of this organism as an alga is uncertain as the taxonomic position of the group of organisms, that includes *Schizochytrium* and the related group of thraustochytrid organisms, continues to be researched. *Schizochytrium*, like *Crypthecodinium cohnii*, is nonphotosynthetic and is also grown in large-scale bioreactors using glucose as substrate. The oil produced is slightly different from the oil of *C. cohnii* in that it contains a small but appreciable percentage of docosapentaenoic acid, 22 : 5 n-6. The full profile of the fatty acids are shown in Table 5.

The Schizochytrium process was originally developed by OmegaTech Ltd, Boulder, CO, which is now owned by Martek Biosciences Corp. The oil was originally given the trade name of DHAGold and was used as an animal feed supplement to boost the content of DHA in the final product. It was particularly useful with poultry where it led to eggs being enriched in DHA and thus, could attract a premium price. The oil itself has now received approval as a direct supplement for humans, including infants, and will, in the future, be used for this purpose. Its current trade name is DHASCO-S.

Some interest has continued in the use of photosynthetically grown algae for polyunsaturated fatty acid production. Although the organisms can be grown outdoors using sunlight as energy source and CO_2 as a carbon source, the costs of production remain very high because of the slow growth rate of the cells and the low cell densities that are produced. It may take four to six weeks to generate algal cells at no more than 5 g L^{-1} in an outdoor system, whereas *Schizochytrium*, as discussed earlier, when grown heterotrophically in a stirred fermenter it can reach biomass densities of up to 200 g L^{-1} in about four days. However, there are still several groups who continue to use microalgae for the production of various fatty acids not easily obtainable from other sources. Of particular interest is the possible production of EPA for which no source, as a single PUFA, currently exists apart from very expensive purification from fish oils that contain both EPA and DHA. The demand for an oil rich in EPA as a single PUFA is likely to increase as it has been recommended for use in the treatment of various disorders of the brain, including bipolar disorder and schizophrenia. There have also been suggestions that a high dosage of EPA may help in the treatment of certain cancers though this is highly contentious. For these reasons, there is likely to be considerable interest in obtaining a good supply of this PUFA from whatever source and, currently, photosynthetic algae appear to offer the best prospects.

Keywords

Apolipoprotein
A protein found on lipoprotein particles that functions to maintain the structural integrity of the lipoprotein particle and to modulate lipoprotein metabolism.

Atherosclerosis
Deposition of lipid in the intimal wall of large- to medium-sized arteries that impinges on blood flow and/or predisposes the vessel to thrombosis.

Cholesterol
A 27-carbon sterol that is a common lipid constituent of cell plasma membranes and lipoproteins.

Coronary Artery Disease
The presence of atherosclerosis in the coronary artery vessels of the heart, which can interfere with blood flow.

Lipoprotein
A small complex of lipid and protein that serves as the main carrier of extracellular lipid.

Lipoproteins are submicron- to micron-sized particles that are composed of both lipids and proteins. Lipoproteins are the major extracellular carrier of lipids, such as cholesterol, and thus, they play an important role in the pathogenesis of atherosclerosis. The analysis of lipoproteins is performed in most clinical laboratories to identify patients at risk of coronary heart disease (CHD). Lipoprotein analysis is also essential in monitoring the effectiveness of cholesterol-lowering therapy.

The focus of this chapter will be on methods for lipoprotein analysis that are used for routine diagnostic purposes, but in addition, new promising types of lipoprotein analysis that are still in the realm of basic research will also be highlighted. A brief description of lipid biochemistry and lipoprotein metabolism will be followed by a review of commonly used methods for analyzing lipoproteins. Finally, the chapter will conclude with a summary of how the results of lipoprotein analysis are used in the diagnosis and management of patients with dyslipidemias.

1 Overview of Lipoproteins

1.1 Lipid Biochemistry

Lipids, commonly referred to as *fats*, are composed of mostly carbon and hydrogen (Fig. 1), and are therefore hydrophobic. Two major classes of lipids, based on their relative hydrophobicity, are found on lipoproteins. Phospholipids and cholesterol are classified as amphipathic lipids because, in addition to C-H bonds, they also contain polar groups. In contrast,

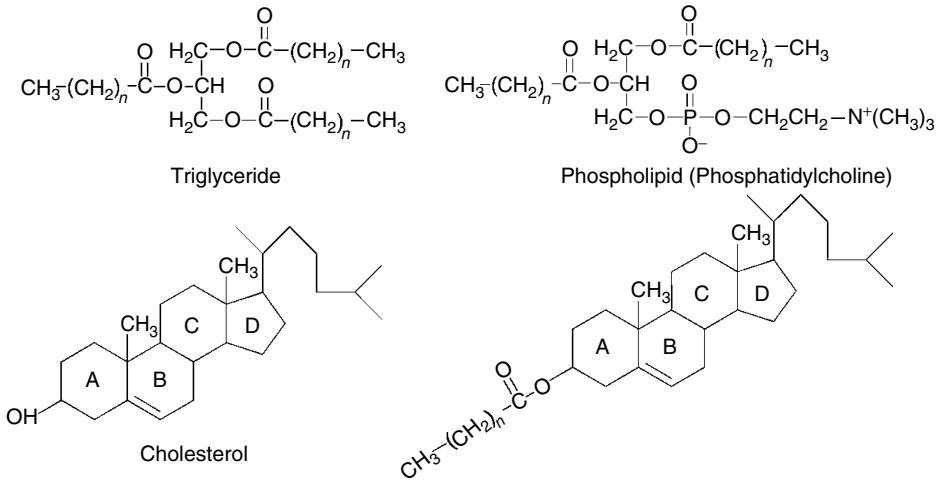

Fig. 1 Chemical structures of lipids found on lipoproteins.

cholesteryl esters and triglycerides do not contain any polar constituents and are therefore more hydrophobic and are classified as neutral lipids.

A prototypical structure of a lipoprotein particle is shown in Fig. 2. Phospholipids and cholesterol form a monolayer on the surface of lipoprotein particles. Phospholipids are oriented so that their charged head groups are facing outward, away from the neutral hydrophobic core. Cholesterol is also oriented so that its polar hydroxyl group on the A ring (Fig. 1) is pointing away from the lipoprotein surface. Cholesteryl esters and triglycerides are found in the core of lipoprotein particles in a disorganized liquid crystalline state.

Except for cholesterol, all of the other major lipids found on lipoprotein have numerous distinct chemical forms (Fig. 1). The different forms of triglyceride can be identified on the basis of the type of fatty acids that they contain. Fatty acids can be classified on the basis of the number of carbon atoms as short-chain (4–6 carbon atoms), medium-chain (8–12 carbon atoms), or long-chain (>12 carbon atoms) fatty acids. Most dietary fatty acids are long chain and contain an even number of carbon atoms. Fatty acids also differ on the basis of the number of unsaturated or double carbon bonds that they contain. Fatty acids with no double bonds are classified as saturated fatty acids, whereas fatty acids with one double bond are monounsaturated and fatty acids with two or more double bonds are polyunsaturated. The different fatty acids are commonly designated by their carbon-chain length and by the number of double bonds. For example, arachidonate, a polyunsaturated fatty acid that has 20 carbon atoms and 4 double bonds is designated as 20 : 4. The common fatty acids found in human serum triglycerides are palmitate (16 : 0), oleate (16 : 1), and stearate (18 : 0). Triglycerides containing shorter chain fatty acids or unsaturated fatty acids have a lower melting point and are usually liquid at room temperature. Saturated fatty acids are commonly found in food from animal sources, whereas unsaturated fatty acids are abundant in food derived from plants.

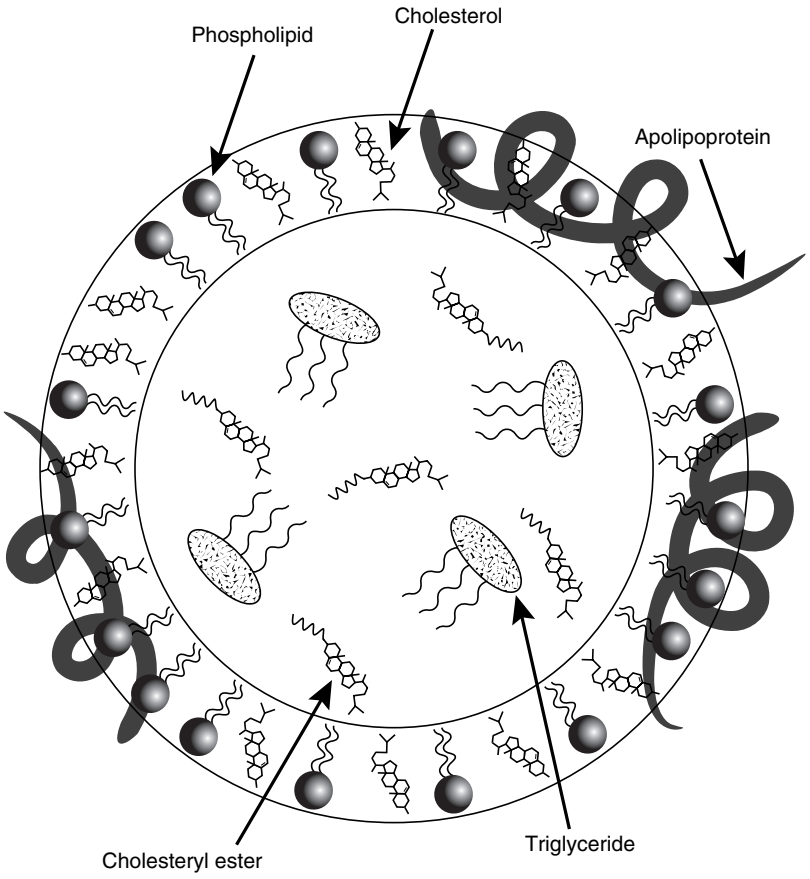

Fig. 2 Model of lipoprotein particle.

Similar to triglycerides, there are different forms of cholesteryl esters, depending on the type of fatty acid that is esterified to the A ring of cholesterol. Cholesteryl linoleate, which is primarily produced by the serum enzyme lecithin: cholesterol acyltransferase (LCAT), and cholesteryl oleate, which is primarily produced by the intracellular enzyme acylcoenzyme A: cholesterol acyltransferase (ACAT), are the two most common forms of cholesteryl esters in humans.

Phospholipids can differ not only by the type of fatty acids that they contain but also by their different head groups (choline, inositol, serine, glycerol, and ethanolamine), which serves as the basis for their nomenclature. Phosphatidylcholine (Fig. 1), which contains a choline head group, is the most common type of phospholipid found on lipoproteins.

1.2 Lipoprotein Structure and Function

Lipoproteins are typically spherical in shape and range in size from 5 to 1200 nm (Table 1). In addition to lipids, lipoproteins also contain proteins, called *apolipoproteins*, which reside on the surface of

lipoprotein particles (Fig. 2). Apolipoproteins can serve both a structural role in maintaining the integrity of the lipoprotein particle and also a functional role in lipoprotein metabolism. Apolipoproteins contain a structural motif called an *amphipathic helix*, which enables them to bind to lipids. Amphipathic helices are α-helices with approximately half of the helix composed of hydrophilic amino acid residues and the other half composed of hydrophobic amino acid residues. They are oriented on the surface of lipoprotein particles to allow the interaction of the hydrophobic face of the helix with the surface lipids. Apolipoproteins also play a major role in modulating lipoprotein metabolism by acting as ligands for various lipoprotein receptors and by acting as activators and inhibitors of several lipid-modifying enzymes (Table 2).

Several different classification systems based on their varying physical properties can be used for categorizing lipoprotein particles. A density classification system (Chylomicrons (Chylos), very low density

lipoproteins (VLDL), intermediate density lipoproteins (IDL), low density lipoproteins (LDL), and high density lipoproteins (HDL)), which was developed on the basis of the original ultracentrifugation system for isolating lipoproteins, is most common (Table 1). The size of the lipoprotein particles is inversely related to their density. Larger lipoprotein particles have relatively more core lipid and less protein and are, therefore, lighter in density.

Three major pathways in lipoprotein metabolism and how the different types of lipoprotein particles are involved in each pathway are shown in Fig. 3. Chylomicrons are the largest and the least-dense lipoprotein particles and contain a single molecule of apoB-48 as well as several other types of apolipoproteins (Table 2). Chylomicrons are produced by the intestine and they participate in the exogenous pathway, which delivers dietary lipids to the liver and to other peripheral tissues. The turbidity of postprandial serum is due to the presence of chylomicrons, which reflect light because of their large size. Once chylomicrons enter the circulation, they are quickly catabolized within a few hours by lipoprotein lipase (LPL) and hepatic lipase (HL), which are on the surface of endothelial cells and hydrolyze triglycerides and phospholipids (Fig. 3). The free fatty acids that are generated are taken up by tissues and are either reesterified and stored in lipid drops or are used as a source of energy. Chylomicrons are transformed by this process into the more dense chylomicron remnants, which are primarily removed by the liver via a chylomicron remnant receptor that binds apoE.

VLDL, IDL, and LDL participate in the endogenous pathway of lipid metabolism, which transports hepatic-derived lipids to peripheral tissues (Fig. 3). VLDL has a single copy of apoB-100; it is produced in the liver and is rich in triglycerides synthesized by the liver. Like chylomicrons, the core lipids of VLDL are acted upon by LPL and HL, and the fatty acids released are taken up by peripheral tissues. As a consequence of the lipolysis, a significant fraction of VLDL is transformed into IDL and ultimately into LDL. The majority of LDL is returned to the liver via the LDL receptor; however, LDL can also be taken up in peripheral tissues by the LDL receptor.

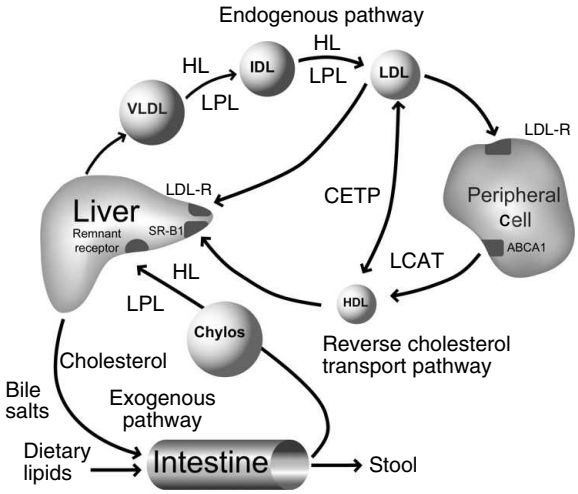

Fig. 3 Diagram of lipoprotein metabolism.

Because of its small size, LDL can also readily infiltrate into the vessel wall and become trapped there by proteoglycans. LDL in the vessel wall is prone to oxidation, which then makes it a better ligand for scavenger receptors on macrophages. Macrophages that take up too much lipid become filled up with intracellular lipid drops and are transformed into foam cells. A collection of foam cells in the vessel walls forms a fatty streak, which is an early precursor of atherosclerotic plaques. Oxidized LDL can also initiate the inflammation of the vessel wall by acting as a chemotactic agent and by inducing the production of various proinflammatory cytokines by macrophages. Another proatherogenic lipoprotein similar to LDL in structure is Lipoprotein (a) (Lp(a)). It contains a single copy of apoB-100, which is covalently linked by a disulfide bond to apo (a), a plasminogen-like protein of unknown function.

High-density lipoprotein is the principal lipoprotein that mediates the reverse cholesterol-transport pathway, delivering the excess cholesterol in peripheral cells back to the liver for excretion (Fig. 3). Because most peripheral cells cannot catabolize cholesterol, the reverse cholesterol-transport pathway is one of the main mechanisms for maintaining cellular cholesterol homeostasis. The principal apolipoprotein on HDL is apoA-I, which is sometimes used as a marker for HDL. In contrast to LDL, HDL has anti-inflammatory properties and is considered to be antiatherogenic because it also mediates the removal of excess cholesterol from peripheral cells. The process of reverse cholesterol transport is initiated when lipid-poor apoA-I interacts with the ABCA1 transporter on the cell surface and extracts excess cholesterol from cells. Cholesterol that is removed from cells is then trapped on HDL after it is transformed into cholesteryl ester by LCAT (Fig. 3). HDL cholesterol is then returned either directly to the liver by the SR-B1 receptor or indirectly after being transferred to LDL by the cholesteryl ester transfer protein (CETP) (Fig. 3).

2 Analysis of Lipoprotein Components

The initial analysis of lipoproteins usually begins with a direct measurement of total cholesterol and triglyceride from serum or plasma, without any prior extraction or fractionation step. Apolipoproteins can also be measured directly on serum or plasma. There are several chemical methods for measuring the various lipids on lipoproteins, which are still used as reference methods by the Centers for Disease Control and Prevention (CDC) and the associated Cholesterol Reference Method Laboratory Network (CRMLN). These chemical methods, however, are complex, laborious, and expensive to perform and have largely been replaced in routine clinical laboratories by automated enzymatic methods.

2.1 Total Cholesterol Assay

A coupled enzyme reaction (Fig. 4), which depends on the specificity of cholesterol oxidase for cholesterol, is the most common enzyme method for measuring total cholesterol. Before measuring cholesterol, cholesteryl ester, which makes up about two-thirds of total cholesterol, is first converted to free cholesterol by cholesteryl esterase. The free cholesterol generated then reacts with cholesterol oxidase, which results in the production of cholestenone

- Cholesteryl ester + H_2O $\xrightarrow{\text{Cholesteryl esterase}}$ Cholesterol + Fatty acid
- Cholesterol + O_2 $\xrightarrow{\text{Cholesterol oxidase}}$ Cholestenone + H_2O_2
- H_2O_2 + Dye $\xrightarrow{\text{Cholesterol oxidase}}$ Color

Fig. 4 Enzymatic assay for cholesterol.

and hydrogen peroxide. The amount of cholesterol in the sample is quantified by measuring the amount of hydrogen peroxide generated by using a horseradish peroxidase–dye system (Fig. 4). The assay is monitored spectrophotometrically at approximately 500 nm and can be performed on serum or plasma without any prior extraction with an organic solvent. Modern reagents include other constituents that eliminate most sources of interference, although specimens with marked elevations of vitamin C or bilirubin and specimens with gross hemolysis can experience interference with the peroxidase catalyzed color reaction. Most commercial assays are developed for specific analyzers and should yield results within 3% of the result obtained by the reference method, with a coefficient of variation of less than 3%. Although it is not frequently performed for diagnostic purposes, free (nonesterified) cholesterol can be simply measured by omitting the cholesterol ester–hydrolase step.

2.2 Triglyceride Assay

There are several different colorimetric enzyme assays for triglycerides, which primarily differ in how they are coupled to an indicator dye. As shown in Fig. 5, all of these methods begin with the enzymatic hydrolysis of fatty acid from the glycerol backbone, with a lipase. In one of the more common methods (Fig. 5), the amount of triglyceride is measured by quantifying the glycerol, using glycerokinase and glycerophosphate oxidase and the same dye-peroxidase system used in the cholesterol assay. One problem with this approach is that the assay will also measure any endogenous free glycerol in a sample. For most samples, this will result in a clinically insignificant positive bias of less than 10 to 20 mg dL^{-1}, but in some disorders, such as diabetes, or in patients receiving total parenteral nutrition, the bias can become clinically significant. It is for this reason

- Triglyceride + H_2O $\xrightarrow{\text{Bacterial lipase}}$ Fatty acid + Glycerol
- Glycerol + ATP $\xrightarrow{\text{Glycerokinase}}$ Glycerophosphate + ADP
- Glycerophosphate + O_2 $\xrightarrow{\text{Glycerophosphate oxidase}}$ Dihydroxyacetone + H_2O_2
- H_2O_2 + Dye $\xrightarrow{\text{Peroxidase}}$ Color

Fig. 5 Enzymatic assay for triglyceride.

that some laboratories compensate for this problem by measuring and correcting for the free glycerol in a blanking procedure or by performing an assay that consumes any free glycerol in the first step, thus eliminating the measurement of any endogenous glycerol later on in the reaction. Alternatively, the manufacturers of some triglyceride assays compensate for this bias by adjusting the value of their calibrators.

2.3 Phospholipid Assay

The measurement of phospholipids has not been shown to have any diagnostic value and is commonly done only in research laboratories. The choline-containing phospholipids, lecithin, lysolecithin, and sphingomyelin, account for at least 95% of total phospholipids in serum and can be measured enzymatically with commercial kits, using phospholipase D, choline-oxidase, and horseradish peroxidase. To measure total phospholipids, independent of the head group, phosphorus is measured chemically after it is released by acid hydrolysis from an extracted sample. The individual types of phospholipids can be measured semiquantitatively after separation by thin-layer chromatography.

2.4 Apolipoprotein Assays

Because of their relatively unique distribution on the different lipoprotein particles (Table 2), apoA-I and apoB-100 in serum are used as an index of the amount of HDL and LDL respectively. Because these two proteins are relatively abundant, they can be measured with specific antibodies by either turbidometric or nephelometric procedures. These assays are now routinely available on standard clinical analyzers and are free from most interferences except for problems related to light scattering from turbid samples with elevated chylomicrons and VLDL. Tests for apoA-I and apoB-100 have been shown to be more precise and accurate than tests for HDL-C and LDL-C. The apolipoproteins have been proposed as being possibly superior for predicting CHD (coronary heart disease) risk, but they have not yet been incorporated into the National Cholesterol Education Program (NCEP) practice guidelines for lipoprotein analysis.

The proatherogenic Lp(a) lipoprotein can also be measured by quantifying the presence of the apo(a) apolipoprotein, using various ELISA or nephelometric methods. There are, however, different size polymorphisms of apo(a), which complicate the immunologic measurement and differ in their correlation with CHD risk. A qualitative assessment of isoform distribution by electrophoresis or by genotyping is also used for characterizing Lp(a) and for estimating CHD risk.

3 Fractionation of Lipoproteins

Numerous methods for fractionation of the various lipoproteins have been developed on the basis of their different physical properties, such as size, density, charge, solubility, and apolipoprotein content. Historically, ultracentrifugation was the primary means of separating the different lipoprotein fractions on the basis of density and is still the foundation of the current lipoprotein classification system (Table 1). The primary reason for fractionating lipoproteins is to provide a measure

of their relative abundances. Fractionation is particularly useful for measuring the cholesterol content of LDL (LDL-C) and HDL (HDL-C), which are used in calculating CHD risk. Electrophoresis is the other commonly used method in clinical laboratories for fractionating lipoproteins.

3.1 HDL-C Assays

Until recently, the most common method for measuring HDL-C has been a multistep precipitation procedure, which involved the removal of apoB-containing lipoproteins (chylos, VLDL, IDL, LDL, and Lp(a)) by precipitation and centrifugation, followed by the enzymatic measurement of cholesterol in the supernatant. A wide variety of polyanions, such as heparin, phosphotungstate, and dextran sulfate will bind to positively charged groups on apoB-containing lipoproteins and cause their aggregation and precipitation, in the presence of divalent cations, such as manganese and magnesium. Magnesium has become the divalent cation of choice because of interference with enzymatic lipid assays by manganese. Numerous commercial assays have been developed with the different precipitating reagents. Initially, results from these different assays often yielded discordant results, but this problem has largely been resolved by the ongoing efforts to improve the standardization of lipoprotein assays.

A major limitation of the various HDL-precipitation methods is that specimens with elevated triglycerides often have a positive bias for HDL-C. Because of their low density, specimens with high levels of chylomicrons and triglyceride-rich VLDL will often form aggregates that do not fully sediment upon centrifugation. This leads to a false elevation for HDL-C, because, when cholesterol is measured in the supernatant, not only cholesterol from HDL is measured but cholesterol from any residual aggregates is also measured. This problem can at least be partially solved by predilution of the sample, which facilitates the sedimentation of the aggregates. Although it is laborious, ultracentrifugation or ultrafiltration of the sample to remove any residual aggregates will also eliminate this source of bias.

Unlike the precipitation-based HDL-C tests, most other commonly measured clinical laboratory tests do not require any significant specimen preprocessing. This limitation of the HDL-C-precipitation tests has prompted the recent development of homogenous assays for HDL-C that can be performed directly on serum or plasma, without the physical removal of non-HDL lipoproteins. These assays work by using reagents that chemically mask the non-HDL lipoproteins during the enzymatic measurement of cholesterol associated with HDL. This can be accomplished by using different strategies that involve the use of polymers, detergents, antibodies, or even modified enzymes. These various reagents bind to non-HDL lipoproteins and block their accessibility to cholesterol esterase and cholesterol oxidase. Other homogenous assays selectively deplete non-HDL-C in the first step, thus preventing its measurement later on in the reaction. Several commercial homogenous HDL-C assays are now available on automated instruments, and these assays show relatively good accuracy and typically better precision than precipitation-based assays. Precipitation-based HDL-C assays have now largely been replaced by homogenous HDL-C assays in most routine clinical laboratories, but they still have a role in research laboratories and in specialty lipid laboratories because the

homogenous HDL-C assays do not always yield good results in patients with unusual dyslipidemias and/or in patients with severe liver or kidney disease.

3.2 LDL-C Assays

Traditionally, methods for measuring LDL-C have been more difficult to perform than HDL-C assays because there is no convenient precipitation procedure to cleanly separate LDL from the other apoB-containing lipoproteins. As a consequence, the original LDL-C methods involved a procedure commonly referred to as *β-quantification*, which involves both a precipitation and an ultracentrifugation step. In the first step, chylomicrons and VLDL are removed from a sample by ultracentrifugation (105 000 G for 18 h at 10 °C) at the native density of plasma (1.006 g L^{-1}), which results in their flotation at the top of the tube. Chylomicrons and VLDL are then removed with a tube slicer and cholesterol in the infranate, which consists of HDL-C and LDL-C, is measured using an enzymatic assay. HDL-C is then measured either from the infranate or from the original sample after precipitation and removal of LDL. LDL-C is calculated by subtracting HDL-C from the cholesterol value obtained from the infranate. The β-quantification method serves as the basis for the LDL-C reference method, but because of its complexity and the requirement of an ultracentrifuge, the procedure is primarily used by specialty lipid laboratories.

Instead of directly measuring LDL-C, most clinical laboratories calculate it from the results of a fasting sample, using the following Friedewald equation: (LDL-C = Total cholesterol – (HDL-C + triglyceride/5); all units in mg dL^{-1}). In a fasting sample without chylomicrons, cholesterol can be mostly found in LDL, HDL, and VLDL and triglycerides are mostly found in VLDL. The term triglyceride/5 in the equation has been shown to closely approximate VLDL-C because there is about five times more triglyceride than cholesterol in a typical VLDL particle when both values are expressed in units of mg dL^{-1}. LDL-C can, therefore, be simply calculated by subtracting the measured HDL-C and the calculated VLDL-C from the measured total cholesterol. However, the Friedewald equation has been shown to yield inaccurate results in samples that have VLDL particles with abnormal lipid composition. This rarely occurs but can be observed in patients with fasting triglycerides greater than 400 mg dL^{-1}, who have triglyceride-rich VLDL, and in patients with type-III hyperlipidemia, who have cholesterol-rich VLDL. Thus, by the Friedewald equation, LDL-C can be reasonably estimated in most samples by simply measuring total cholesterol, triglyceride, and HDL-C. These three tests and the calculated LDL-C comprise what has now become commonly known as a "lipid panel."

One potential limitation of both the β-quantification procedure and the Friedewald calculation is that they both measure, in addition to LDL-C, the relatively small amounts of cholesterol that are associated with Lp(a) and IDL. In addition, the β-quantification procedure is complex and there have been concerns about the precision and accuracy of the Friedewald equation because of the cumulative effect of errors in the three underlying tests that are used in the calculation. These limitations have led to the development of direct homogenous LDL-C assays. Like the homogenous HDL-C assays, these assays use reagents that selectively block or solubilize and consume the different lipoprotein

classes, allowing the direct measurement of LDL-C from an unfractionated sample. Several automated commercial homogenous LDL-C assays are currently available. In general, these assays show good precision and appear to be accurate on normal specimens. Homogenous LDL-C assays, however, have not yet replaced the use of calculated LDL-C in most clinical laboratories for several reasons. First, the homogenous LDL-C assays are relatively new and, in many cases, have not been fully evaluated in patients with the full spectrum of dyslipidemias. Early results, in fact, suggest that the homogenous LDL-C assays are not highly specific in their separation of the various lipoproteins and do not consistently agree with β-quantification and are typically no more reliable than Friedewald calculation. In addition, because the three tests that make up the lipid panel are usually necessary for a complete lipoprotein evaluation, it has not yet been clearly established that performing a separate direct test for LDL-C offers any real advantages in the diagnosis and management of patients with dyslipidemias.

3.3 Electrophoresis of Lipoproteins

Electrophoresis is a relatively convenient method for separating the major classes of lipoproteins. Electrophoresis of lipoproteins can be performed on a variety of matrices, but separation on agarose gels is relatively easy to perform and it readily resolves the major lipoprotein classes on the basis of both size and charge. Some typical electrophoretic patterns of lipoproteins are shown in Fig. 6. HDL shows the fastest migration on agarose gels and migrates to what is called the *α-position*. Chylomicrons barely migrate past the origin of the gel, and LDL typically migrates to the intermediate β-position. VLDL migrates to the pre-β-position between HDL and LDL, but in type-III hyperlipidemia, it usually migrates as a broad band in the β-region. The lipoproteins in agarose gels are usually stained with a dye that stains neutral lipids, such as Oil Red O.

Early on, the electrophoretic separation of lipoproteins was an important diagnostic tool because the original phenotypic classification of dyslipidemias was based on this method. With the discovery of the genetic basis of many of the common dyslipidemias and with the advent of more specific tests, a genetic classification of lipoproteins is now more commonly used. As a consequence, electrophoresis is no longer as valuable diagnostically, but it is still useful for identifying and monitoring patients with rare variants of dyslipidemias. Standard electrophoretic methods are also only semiqualitative, which limits their use. Recently, however, commercial

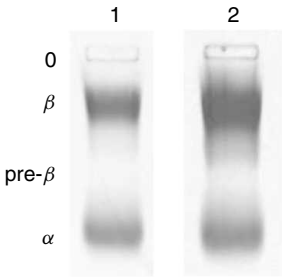

Fig. 6 Agarose gel electrophoresis of a normal subject (Lane 1) and a patient with familial hypercholesterolemia, with an elevated LDL (Lane 2).

automated electrophoretic systems have been developed, which have been shown to be relatively precise and accurate in quantifying the major lipoprotein fractions. There has also been a recent resurgence in the interest of electrophoretic techniques for separating lipoproteins because of their ability to resolve subfractions within each of the major lipoprotein classes.

3.4 Subfractionation of Lipoproteins

Besides the major lipoprotein classes shown in Table 2, it is possible to detect distinct subspecies or subclasses within each class. Most of the methods used in fractionation of the major subclasses of lipoproteins can be modified to improve their resolution for performing subfraction analysis. In addition, nuclear magnetic resonance spectroscopy and density gradient ultracentrifugation in a vertical rotor are particularly useful for performing a comprehensive subfraction analysis of lipoproteins. Nondenaturing gradient gel electrophoresis in polyacrylamide is also a good method for separating the subfractions of lipoproteins by size. When combined with agarose gel electrophoresis, in a two-dimensional gel-electrophoresis system, as many as 10 different species of HDL can be observed.

Subfraction analysis of lipoproteins has largely been performed for basic research applications, but increasingly, subfractions within both LDL and HDL have been shown to potentially have diagnostic importance. A subfraction of LDL called *small dense LDL* has been proposed to be particularly proatherogenic. This form of LDL also appears to be at least partly inheritable. Approximately 25% of the Caucasian population has what is called the *subclass B phenotype* of LDL, which is associated with an increase in small dense LDL and an increased risk for CHD.

In the case of HDL, some forms of HDL have been shown to be particularly efficient in promoting reverse cholesterol transport and may even be a stronger negative predictor of CHD than total HDL. One such form is a small lipid-poor form of HDL, which has a pre-β-type migration on agarose gel electrophoresis. Pre-β-HDL can also be measured by an ELISA assay. Unlike other forms of HDL, pre-β-HDL is discoidal in shape because it lacks a central lipid core of neutral lipids. It consists of a bilayer of phospholipids around which apolipoproteins surround the acyl chains of the phospholipids in a beltlike configuration. Pre-β-HDL has been proposed to be particularly antiatherogenic because it is the form of HDL that initially interacts with cells for removing excess cholesterol by the ABCA1 transporter (Fig. 3).

4 Diagnostic Application of Lipoprotein Analysis

4.1 Standardization of Lipoprotein Analysis

There are three important sources of variability or error that can affect the results of lipoprotein analysis, namely, biological, preanalytical, and analytical variability. There has been great improvement in the last several years in analytical systems for measuring lipids and lipoproteins, and systematic biases among the various lipid and lipoprotein assays have significantly decreased over the last several years. This has occurred because of the partnership between the clinical laboratory community, diagnostic companies, and

various governmental regulatory bodies in improving the accuracy of lipoprotein analysis. In order to minimize the misdiagnosis of patients, the National Cholesterol Education Program or NCEP, a National Institute of Health sponsored organization that produces practice guidelines for the diagnosis and treatment of patients for coronary artery disease, has developed accuracy and precision goals for lipoprotein analysis (Table 3). The CDC created the Cholesterol Reference Method Laboratory Network (CRMLN; http://www.cdc.gov/nceh/dls/crmln/crmln.htm), which provides a mechanism for diagnostic companies and routine clinical laboratories to compare the performance of their assays to the reference methods, which are traceable to the definitive assays established by the National Institute of Standards and Technology (NIST). Clinical laboratories are also required, as part of their biannual recertification process, to compare themselves, multiple times each year, to their peers that use the same assays by analyzing unknown control material, through one of the national proficiency testing programs, such as the one offered by the College of American Pathologists. It is also mandatory for clinical laboratories to test their assays daily by measuring control materials. In addition, it is important to use a reagent system with an analyzer for which the assay has been developed, in order to ensure the proper performance of the assay. Because of the underlying errors in total cholesterol and HDL-C assays, it is often particularly difficult, however, for routine clinical laboratories to achieve the NCEP accuracy goals for LDL-C by using the Friedewald equation. Further improvements are considered necessary in the current total cholesterol and HDL-C assays or in direct LDL-C assays to improve the accuracy and precision of LDL-C measurements.

It is important also to consider preanalytical sources as a source of error. It is recommended that a blood sample be collected from subjects in a sitting position because posture can affect the results of lipoprotein analysis, through changes in hemoconcentration. In addition, different types of collection tubes can lead to differences in results. Most clinical laboratories use serum for their analysis, but EDTA plasma is often preferred when lipoproteins are isolated by ultracentrifugation because EDTA helps reduce proteolysis and oxidation of the lipoproteins. EDTA in the collection tube will, however, cause slight dilution of the sample because it increases the osmotic strength of plasma, which causes water from red blood cells to shift to the plasma compartment. Lipoprotein results from EDTA plasma should, therefore, be multiplied by 1.03 to match serum results.

Tab. 3 NCEP analytical performance goals.

	Precision	***Bias***	***Total error***
Total cholesterol:	3% CV	±3%	±8.9%
HDL cholesterol:			
$\geq$42 mg dL^{-1}	4% CV	±5%	±12.8%
<42 mg dL^{-1}	SD < 1.7 mg dL^{-1}		
LDL cholesterol:	4% CV	±4%	±11.8%
Triglycerides:	5% CV	±5%	±14.8%

Other types of anticoagulants also have varying osmotic effects. Fasting (9–12 h) specimens are preferred for lipoprotein analysis because of problems related to measuring LDL-C in the presence of high triglycerides and because of the changes that occur in the lipoprotein levels in the postprandial state.

There is also a large biological variability for lipids and lipoproteins. For total cholesterol, the coefficient of variation for biological variability is approximately 6% so that results from the same individual that are collected only a few days apart can vary by as much as 12%. For triglycerides, the coefficient of biological variability is as large as 20%. Some of the potential sources of biological variability include effects due to acute or subacute illnesses, changes in diet, exercise frequency, body weight, or smoking. It is for this reason that the NCEP recommends that any treatment decisions be based on the average of two to three test results that should be taken at least 2 weeks apart to reduce the effect of any biologic and analytical variability.

4.2 Interpretation of Lipoprotein Assay Results

Adult reference range of lipids and lipoproteins are shown in Table 4. Unlike most other laboratory-test results, these reference ranges do not represent the central 95% interval. For example, approximately 50% of the adult US population has a total cholesterol value greater than the upper limit of 200 mg dL^{-1}. The reference values for lipids and lipoproteins instead represent the ideal test range chosen by expert consensus for reducing the risk of developing cardiovascular disease.

A flowchart of how lipoprotein analysis is used in implementation of the NCEP-III guidelines (http://www.nhlbi.nih.gov/about/ncep) for the diagnosis and treatment of cardiovascular disease is shown in Fig. 7. These guidelines represent the consensus of an expert panel on the scientific literature supporting the treatment of dyslipidemia for the prevention of CHD. It is recommended that a complete lipid

Tab. 4 Adult reference ranges for lipids.

Total cholesterol	140–200 mg dL^{-1}
HDL-C	40–75 mg dL^{-1}
LDL-C	50–130 mg dL^{-1}
Triglyceride	60–150 mg dL^{-1}

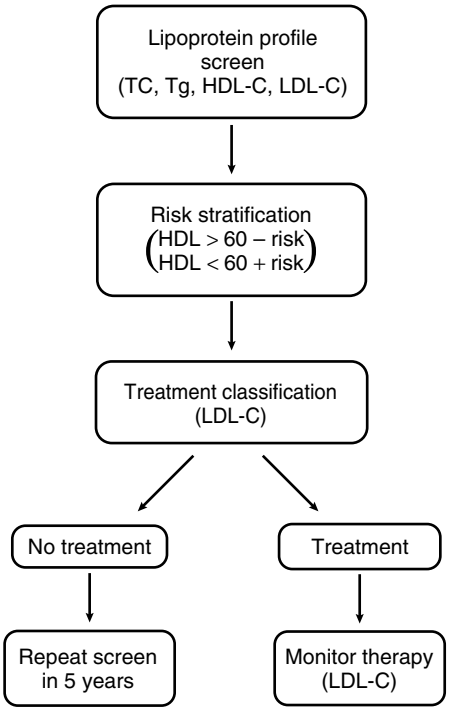

Fig. 7 Flow chart on the use of lipoprotein analysis in NCEP-III guidelines for the diagnosis and treatment of dyslipidemia.

panel test (total cholesterol, triglycerides, HDL-C, and a calculated LDL-C) be performed, as part of the initial screen, on a 9 to 12 h fasting sample. If the total triglycerides are more than 400 mg dL^{-1}, a β quantitation of LDL-C may be necessary or, possibly, a direct LDL-C test. For nonfasting samples, just a total cholesterol and HDL-C test should be performed. If the total cholesterol is less than 200 mg dL^{-1} and the HDL-C is greater than 60 mg dL^{-1} on a nonfasting sample and if the patient is at low risk for CHD, no further analysis is recommended. Each subject is then stratified into four levels of risk for CHD. This stratification is based on previous history of cardiovascular disease and/or its risk equivalent, such as diabetes, as well as other known risk factors for CHD, such as hypertension, smoking, and family history. HDL-C is also used in this risk stratification process. HDL-C greater than 60 mg dL^{-1} is used as a negative risk factor, whereas HDL-C less than 40 mg dL^{-1} is used as a positive risk factor. Each patient is then categorized into a treatment category on the basis of his or her LDL-C. Each level of risk has an ideal upper limit for LDL-C, and the LDL-C limit is set lower for those patients at higher risk. Initially, all patients that have an LDL-C that exceeds the recommended level are counseled to initiate lifestyle changes, such as reducing weight, increasing physical activity, and switching to a low-fat diet. If the lifestyle changes are ineffective in reaching the desirable range of LDL-C and/or if patients have an LDL-C that is beyond a recommended drug-treatment threshold for LDL-C, concurrent treatment with drugs to lower cholesterol is also recommended. The effect of any therapy is monitored, thereafter, by measuring LDL-C. HDL-C and triglycerides may also be important to be monitored, depending on their pretreatment levels and the type of drug therapy used. Other newly developed lipoproteins tests, such as Lp(a), remnant lipoproteins, small dense LDL, and tests for other markers of coronary artery disease, such as CRP and homocysteine, are currently not used in the initial risk stratification of a patient but these can be considered when making treatment decisions. For patients at the lowest risk for CHD, with an LDL-C below 160 mg dL^{-1}, no treatment is recommended and a repeat screen should be performed within 5 years.

5 Perspective

Nearly 50 years have passed since the first methods were developed for separating and analyzing lipoproteins by ultracentrifugation. During this time, great advances have been made in unraveling the various pathways of lipoprotein metabolism and the role of the individual lipoproteins. This has been coupled with the identification and elucidation of many of the genetic causes of dyslipidemias. Of paramount importance have been the epidemiological and animal studies that have revealed the causal association between lipoproteins and coronary heart disease. In many cases, advances in analytical techniques for lipoprotein analysis were pivotal to these discoveries. On the basis of the rapid advances to date in lipoprotein analysis, it is envisioned that there will be many future improvements in these tests, which will lead to even more detailed insights into lipoprotein metabolism and diagnostic tests with even greater clinical utility for preventing coronary heart disease.

Keywords

Colloidal Suspensions
The density of complexes in a specific volume.

Formulation
Procedures used to make liposomes and complexes.

Gene Therapy
Treatments that are mediated by either the addition of needed genes or the destruction of transcripts encoding unwanted gene products.

Lamellar Structures
Alternation of a lipid bilayer and a water layer.

Liposomes
Bilayers made from lipids.

Nonviral Delivery
Delivery vehicles that are not viruses or any other live organism.

Optimization
Creation of optimal conditions.

Serum Stability
Complexes that do not precipitate in specific percentage of serum.

Systemic Delivery
Delivery in the bloodstream.

Varied results have been obtained using cationic liposomes for *in vivo* delivery. Furthermore, optimization of cationic liposomal complexes for *in vivo* applications is complex involving many diverse components. These components include nucleic acid purification, plasmid design, formulation of the delivery vehicle, administration route and schedule, dosing, detection of gene expression, and others. This chapter will also focus on optimization of the delivery vehicle formulation. These formulation issues include morphology of the complexes, lipids used, flexibility versus rigidity, colloidal suspension, overall charge, serum stability, half-life in circulation, biodistribution, delivery to and dissemination throughout target tissues. Broad assumptions have been frequently made on the basis of the data obtained from focused studies using cationic liposomes. However, these assumptions do not necessarily apply to all delivery vehicles and, most likely, do not apply to many liposomal systems when considering these other key components that influence the results obtained *in vivo*. Optimizing all components of the delivery system is pivotal and will allow broad use of liposomal complexes to treat or cure human diseases or disorders. This chapter will highlight the features of liposomes that contribute to successful delivery, gene expression, and efficacy.

1 Introduction

Many investigators are focused on the production of effective nonviral gene therapeutics and on creating improved delivery systems that mix viral and nonviral vectors. Use of improved liposome formulations for delivery *in vivo* is valuable for gene therapy and would avoid several problems associated with viral delivery. Delivery of nucleic acids using liposomes is promising as a safe and nonimmunogenic approach to gene therapy. Furthermore, gene therapeutics composed of artificial reagents can be standardized and regulated as drugs rather than as biologics. Cationic lipids have been used for efficient delivery of nucleic acids to cells in tissue culture for several years. Much effort has also been directed toward developing cationic liposomes for efficient delivery of nucleic acids in animals and in humans. Most frequently, the formulations that are best to use for transfection of a broad range of cell types in culture are not optimal for achieving efficacy in small and large animal disease models.

Much effort has been devoted to the development of nonviral delivery vehicles due to the numerous disadvantages of viral vectors that have been used for gene therapy. Following viral delivery *in vivo*, immune responses are generated to expressed viral proteins that subsequently kill the target cells required to produce the therapeutic gene product. An innate humoral immune response can be

produced to certain viral vectors due to previous exposure to the naturally occurring virus. Random integration of some viral vectors into the host chromosome could occur and cause activation of proto-oncogenes, resulting in tumor formation. Clearance of viral vectors delivered systemically by complement activation can also occur. Viral vectors can be inactivated upon readministration by the humoral immune response. Potential for recombination of the viral vector with DNA sequences in the host chromosome that generates a replication-competent infectious virus also exists. Specific delivery of viral vectors to target cells can be difficult because two distinct steps in engineering viral envelopes or capsids must be achieved. First, the virus envelope or capsid must be changed to inactivate the natural tropism of the virus to enter specific cell types. Then, sequences must be introduced that allow the new viral vector to bind and internalize through a different cell surface receptor. Other disadvantages of viral vectors include the inability to administer certain viral vectors more than once, the high costs for producing large amounts of high-titer viral stocks for use in the clinic, and the limited size of the nucleic acid that can be packaged and used for viral gene therapy. Attempts are being made to overcome the immune responses produced by viral vectors after administration in immune competent animals and in humans, such as the use of gutted adenoviral vectors or encapsulation of viral vectors in liposomes. However, complete elimination of all immune responses to viral vectors may be impossible.

Use of liposomes for gene therapy provides several advantages. A major advantage is the lack of immunogenicity after *in vivo* administration, including systemic injections. Therefore, the nucleic acid-liposome complexes can be readministered without harm to the patient and without compromising the efficacy of the nonviral gene therapeutic. Improved formulations of nucleic acid–liposome complexes can also evade complement inactivation after *in vivo* administration. Nucleic acids of unlimited size can be delivered ranging from single nucleotides to large mammalian artificial chromosomes. Furthermore, different types of nucleic acids can be delivered including plasmid DNA, RNA, oligonucleotides, DNA–RNA chimeras, synthetic ribozymes, antisense molecules, RNAi, viral nucleic acids, and others. Certain cationic formulations can also encapsulate and deliver viruses, proteins or partial proteins with a low isoelectric point (pI), and mixtures of nucleic acids and proteins of any pI. Creation of nonviral vectors for targeted delivery to specific cell types, organs, or tissues is relatively simple. Targeted delivery involves elimination of nonspecific charge interactions with nontarget cells and addition of ligands for binding and internalization through target cell surface receptors. Other advantages of nonviral vectors include the low cost and relative ease in producing nucleic acid-liposome complexes in large scale for use in the clinic. In addition, greater safety for patients is provided using nonviral delivery vehicles due to few or no viral sequences present in the nucleic acids used for delivery, thereby precluding generation of an infectious virus. The disadvantage of nonviral delivery systems had been the low levels of delivery and gene expression produced by ''first-generation'' complexes. However, recent advances have dramatically improved transfection efficiencies and efficacy of liposomal vectors. Reviews

of other *in vivo* delivery systems and improvements using cationic liposomes have been published recently.

Cationic liposome–nucleic acid complexes can be administered via numerous delivery routes *in vivo*. Routes of delivery include direct injection (e.g. intratumoral), intravenous, intraperitoneal, intra-arterial, intrasplenic, mucosal (nasal, vaginal, rectal), intramuscular, subcutaneous, transdermal, intradermal, subretinal, intratracheal, intracranial, and others. Much interest has focused on noninvasive intravenous administration because many investigators believe that this route of delivery is the ''holy grail'' for the treatment or cure of cancer, cardiovascular, and other inherited or acquired diseases. Particularly for the treatment of metastatic cancer, therapeutics must reach not only the primary tumor but also the distant metastases.

Optimization of cationic liposomal complexes for *in vivo* applications and therapeutics is complex, involving many distinct components. These components include nucleic acid purification, plasmid design, formulation of the delivery vehicle, administration route and schedule, dosing, detection of gene expression, and others. Often I make the analogy of liposome optimization to a functional car. Of course, the engine of the car, analogous to the liposome delivery vehicle, is extremely important. However, if the car does not have wheels, adequate tyres, and so on, the motorist will not be able to drive the vehicle to its destination. This chapter will focus on optimization of these distinct components for use in a variety of *in vivo* applications. Optimizing all components of the delivery system will allow broad use of liposomal complexes to treat or cure human diseases or disorders.

2 Optimization of Cationic Liposome Formulations for Use *in vivo*

Much research has been directed toward the synthesis of new cationic lipids. Some new formulations led to the discovery of more efficient transfection agents for cells in culture. However, their efficiency measured *in vitro* did not correlate with their ability to deliver DNA after administration in animals. Functional properties defined *in vitro* do not assess the stability of the complexes in plasma or their pharmacokinetics and biodistribution, all of which are essential for optimal activity *in vivo*. Colloidal properties of the complexes, in addition to the physicochemical properties of their component lipids, also determine these parameters. In particular, in addition to efficient transfection of target cells, nucleic acid–liposome complexes must be able to traverse tight barriers *in vivo* and penetrate throughout the target tissue to produce efficacy for the treatment of disease. These are not issues for achieving efficient transfection of cells in culture with the exception of polarized tissue culture cells. Therefore, we are not surprised that optimized liposomal delivery vehicles for use *in vivo* may be different than those used for efficient delivery to cells in culture.

In summary, *in vivo* nucleic acid–liposome complexes that produce efficacy in animal models of disease have extended half-life in the circulation, are stable in serum, have broad biodistribution, efficiently encapsulate various sizes of nucleic acids, are targetable to specific organs and cell types, penetrate across tight barriers in several organs, penetrate evenly throughout the target tissue, are optimized for nucleic acid:lipid ratio and colloidal suspension *in vivo*, can be size fractionated

to produce a totally homogenous population of complexes prior to injection, and can be repeatedly administered. Recently, we demonstrated efficacy of a robust liposomal delivery system in small and large animal models for lung, breast, head and neck, and pancreatic cancers, and for Hepatitis B and C (Clawson and Templeton, unpublished data). On the basis of efficacy in these animal studies, this liposomal delivery system will be used in upcoming clinical trials to treat these cancers. Our studies have demonstrated broad efficacy in the use of liposomes to treat disease and have dispelled several myths that exist concerning the use of liposomal systems.

3 Liposome Morphology and Effects on Gene Delivery and Expression

Efficient *in vivo* nucleic acid–liposome complexes have unique features including their morphology, mechanisms for crossing the cell membrane and entry into the nucleus, ability to be targeted for delivery to specific cell surface receptors, and ability to penetrate across tight barriers and throughout target tissues. Liposomes have different morphologies based upon their composition and the formulation method. Furthermore, the morphology of complexes can contribute to their ability to deliver nucleic acids *in vivo*. Formulations frequently used for the delivery of nucleic acids are lamellar structures including small unilamellar vesicles (SUVs), multilamellar vesicles (MLVs), or bilamellar invaginated vesicles (BIVs) recently developed in our laboratory (Fig. 1). Several investigators have developed liposomal delivery systems using hexagonal structures; however, they have demonstrated efficiency primarily for the transfection of some cell types in culture and not for *in vivo* delivery. SUVs condense nucleic acids on the surface and form ''spaghetti and meatballs'' structures. DNA–liposome complexes made using SUVs produce little or no gene expression upon systemic delivery, although these complexes transfect

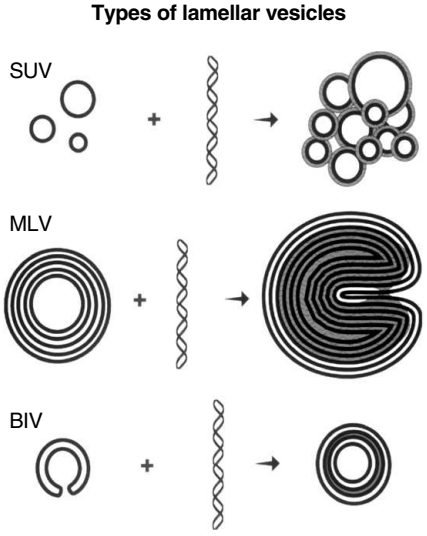

Fig. 1 Diagrams drawn from cryoelectron micrographs of cross sections through vitrified films of various types of liposomes and DNA–liposome complexes. SUVs are small unilamellar vesicles that condense nucleic acids on the surface and produce ''spaghetti and meatballs'' structures. MLVs are multilamellar vesciles that appear as ''Swiss Rolls'' after mixing with DNA. BIVs are bilamellar invaginated vesicles produced using a formulation developed in our laboratory. Nucleic acids are efficiently encapsulated between two bilamellar invaginated structures (BIVs).

numerous cell types efficiently *in vitro*. Furthermore, SUV liposome–DNA complexes cannot be targeted efficiently. SUV liposome–DNA complexes also have a short half-life within the circulation, generally about 5 to 10 min. Polyethylene glycol (PEG) has been added to liposome formulations to extend their half-life; however, PEGylation created other problems that have not been resolved. PEG seems to hinder delivery of cationic liposomes into cells due to its sterically hindering ionic interactions, and it interferes with optimal condensation of nucleic acids onto the cationic delivery vehicle. Furthermore, extremely long half-life in the circulation, for example, several days, has caused problems for patients because the bulk of the PEGylated liposomal formulation doxil that encapsulates the cytotoxic agent, doxorubicin, accumulates in the skin, hands, and feet. For example, patients contract mucositis and ''Hand and Foot Syndrome'' that cause extreme discomfort to the patient. Attempts to add ligands to doxil for delivery to specific cell surface receptors has not resulted in much cell-specific delivery, and the majority of the injected targeted formulation still accumulates in the skin, hands, and feet. Addition of PEG into formulations developed in our laboratory also caused steric hindrance in the bilamellar invaginated structures that did not encapsulate DNA efficiently, and gene expression was substantially diminished.

Some investigators have loaded nucleic acids within SUVs using a variety of methods; however, the bulk of the DNA does not load or stay within the liposomes. Furthermore, most of the processes used for loading nucleic acids within liposomes are extremely time-consuming and not cost effective. Therefore, SUVs are not the ideal liposomes for creating nonviral vehicles for targeted delivery.

Complexes made using MLVs appear as ''Swiss rolls'' when viewing cross-sections by cryoelectron microscopy. These complexes can become too large for systemic administration or deliver nucleic acids inefficiently into cells due to the inability to ''unravel'' at the cell surface. Addition of ligands onto MLV liposome–DNA complexes further aggravates these problems. Therefore, MLVs are not useful for the development of targeted delivery of nucleic acids.

Using a formulation developed in our laboratory, nucleic acids are efficiently encapsulated between two bilamellar invaginated vesicles, BIVs. We created these unique structures using 1,2-bis(oleoyloxy)-3-(trimethylammino)propane (DOTAP) and cholesterol (Chol) and a novel formulation procedure. This procedure is different because it includes a brief, low frequency sonication followed by manual extrusion through filters of decreasing pore size. The 0.1 and 0.2 μm filters used are made of aluminum oxide and not polycarbonate that is typically used by other protocols. Aluminum oxide membranes contain more pores per surface area, evenly spaced and sized pores, and pores with straight channels. During the manual extrusion process, the liposomes are passed through each of the four different sized filters only once. This process produces 88% invaginated liposomes. Use of high-frequency sonication and/or mechanical extrusion produces only SUVs.

The BIVs produced condense, unusually large amounts of nucleic acids of any size Fig. 2 or viruses Fig. 3. Furthermore, addition of other DNA condensing agents including polymers is not necessary. For example, condensation of plasmid DNA onto polymers first before encapsulation in the BIVs did not increase condensation or subsequent gene

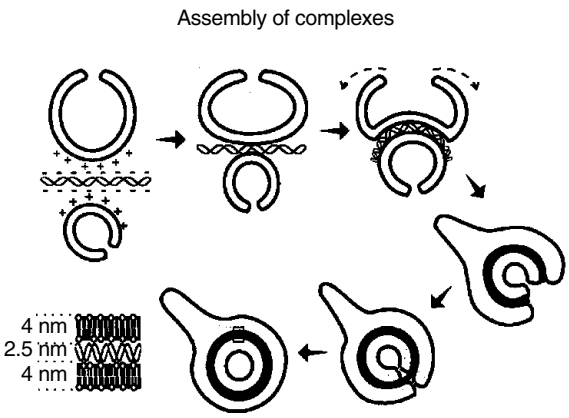

Fig. 2 Proposed model showing cross sections of extruded DOTAP:Chol liposomes (BIVs) interacting with nucleic acids. Nucleic acids adsorb onto a BIV via electrostatic interactions. Attraction of a second BIV to this complex results in further charge neutralization. Expanding electrostatic interactions with nucleic acids cause inversion of the larger BIV and total encapsulation of the nucleic acids. Inversion can occur in these liposomes because of their excess surface area, which allows them to accommodate the stress created by the nucleic acid–lipid interactions. Nucleic acid binding reduces the surface area of the outer leaflet of the bilayer and induces the negative curvature due to lipid ordering and reduction of charge repulsion between cationic lipid headgroups. Condensation of the internalized nucleic acid–lipid sandwich expands the space between the bilayers and may induce membrane fusion to generate the apparently closed structures. The enlarged area shows the arrangement of nucleic acids condensed between two 4 nm bilayers of extruded DOTAP:Chol.

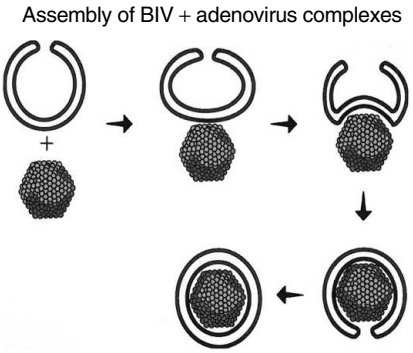

Fig. 3 Proposed model showing cross sections of an extruded DOTAP:Chol liposome (BIV) interacting with adenovirus. Adenovirus interacts with a BIV causing negative curvature and wrapping around the virus particle.

expression after transfection *in vitro* or *in vivo*. Encapsulation of nucleic acids by these BIVs alone is spontaneous and immediate, and, therefore, cost effective, requiring only one step of simple mixing. The extruded DOTAP:Chol–nucleic acid complexes are also large enough so that they are not cleared rapidly by Kupffer cells in the liver and yet extravasate across tight barriers, including the endothelial cell barrier of the lungs in a normal mouse, and diffuse through target organs efficiently. Our recent work demonstrating efficacy for treatment of nonsmall cell lung cancer showed that only BIV DOTAP:Chol-p53 DNA–liposome complexes produced efficacy, and SUV DOTAP:Chol-p53 DNA–liposome complexes produced no efficacy. Therefore, the choice of lipids alone is not sufficient for optimal DNA delivery, and the morphology of the complexes is essential.

4
Optimal Lipids and Liposome Morphology: Effects on Gene Delivery and Expression

Choosing the best cationic lipids and neutral lipids is also essential for producing the optimal *in vivo* formulation. For example, using our novel manual extrusion procedure does not produce BIVs using the cationic lipid dimethyldioctadecylammonium bromide (DDAB). Furthermore, DOTAP is biodegradable, whereas DDAB is not biodegradable. Use of biodegradable lipids is preferred for use in humans. Furthermore, only DOTAP- and not DDAB-containing liposomes produced highly efficient gene expression *in vivo*. DDAB did not produce BIVs and was unable to encapsulate nucleic acids. Apparently, DDAB- and DOTAP-containing SUVs produce similar efficiency of gene delivery *in vivo*; however, these SUVs are not as efficient as BIV DOTAP:Chol. In addition, use of L-α dioleoyl phosphatidylethanolamine (DOPE) as a neutral lipid creates liposomes that cannot wrap or encapsulate nucleic acids. Several investigators have reported efficient transfection of cells in culture using DOPE in liposomal formulations. However, our data showed that formulations consisting of DOPE were not efficient for producing gene expression *in vivo*.

Investigators must also consider the source and lot of certain lipids purchased from companies. For example, different lots of cholesterol from the same vendor can vary dramatically and will affect the formulation of liposomes. Currently, we are using synthetic cholesterol (Sigma, St. Louis, MO). The Food and Drug Administration prefers synthetic cholesterol instead of natural cholesterol that is purified from the wool of sheep for use in producing therapeutics for injection into humans.

Our BIV formulations are also stable for a few years as liquid suspensions. Freeze-dried formulations can also be made that are stable indefinitely even at room temperature. Stability of liposomes and liposomal complexes is also essential, particularly for the commercial development of human therapeutics.

5
Liposome Encapsulation, Flexibility, and Optimal Colloidal Suspensions

A common belief is that artificial vehicles must be 100 nm or smaller to be effective for systemic delivery. However, this belief is most likely true only for large, inflexible delivery vehicles. Blood cells are several microns (up to 7000 nm) in size, and yet have no difficulty circulating in the blood, including through the smallest capillaries. However, sickle cell blood cells, that are rigid, do have problems in the circulation. Therefore, we believe that flexibility is a more important issue than small size. In fact, BIV DNA–liposome complexes in the size range of 200 to 450 nm produced the highest levels of gene expression in all tissues after intravenous injection. Kupffer cells in the liver quickly clear delivery vehicles (including nonviral vectors and viruses) that are not PEGylated and are smaller than 200 nm. Therefore, increased size of liposomal complexes could extend their circulation time, particularly when combined with injection of high colloidal suspensions. BIVs were able to encapsulate nucleic acids and viruses apparently due to the presence of cholesterol in the bilayer (Fig. 4). Whereas, formulations including DOPE instead of cholesterol could not assemble nucleic acids by a ''wrapping

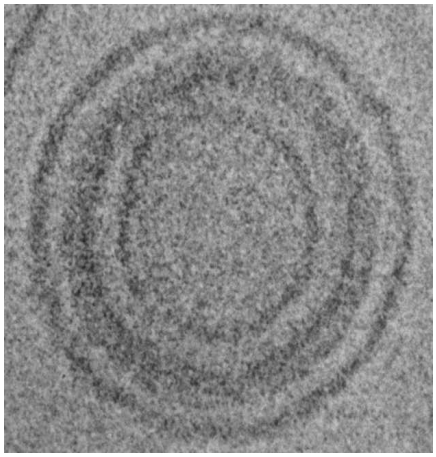

Fig. 4 Cryoelectron micrograph of BIV DOTAP:Chol–DNA–liposome complexes. The plasmid DNA is encapsulated between two BIVs.

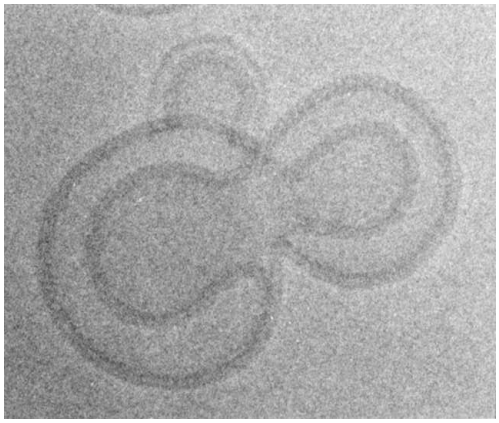

Fig. 5 Cryoelectron micrograph of extruded DOTAP:DOPE liposomes complexed to plasmid DNA. Although these liposomes were prepared by the same protocol that produces BIV DOTAP:Chol, these vesicles cannot wrap and encapsulate nucleic acids. The DNA condenses on the surfaces of the liposomes shown.

type'' of mechanism (Fig. 5), and produced little gene expression in the lungs and no expression in other tissues after intravenous injections. Because the extruded DOTAP:Chol BIV complexes are flexible and not rigid, are stable in high concentrations of serum, and have extended half-life, they do not have difficulty circulating efficiently in the bloodstream.

We believe that colloidal properties of nucleic acid–liposome complexes also determine the levels of gene expression produced after *in vivo* delivery. These properties include the DNA:lipid ratio that determines the overall charge density of the complexes and the colloidal suspension that is monitored by its turbidity. Complex size and shape, lipid composition and formulation, and encapsulation efficiency of nucleic acids by the liposomes also contribute to the colloidal properties of the complexes. The colloidal properties affect serum stability, protection from nuclease degradation, blood circulation time, and biodistribution of the complexes.

Our *in vivo* transfection data showed that an adequate amount of colloids in suspension was required to produce efficient gene

expression in all tissues examined. The colloidal suspension is assessed by measurement of adsorbance at 400 nm using a spectrophotometer optimized to measure turbidity. Our data showed that transfection efficiency in all tissues corresponded to OD400 of the complexes measured prior to intravenous injection.

6 Overall Charge of Complexes and Entry into the Cell

In addition, our delivery system is efficient because the complexes deliver DNA into cells by fusion with the cell membrane and avoid the endocytic pathway (Fig. 6). Cells are negatively charged on the surface, and specific cell types vary in their density of negative charge. These differences in charge density can influence the ability of cells to be transfected. Cationic complexes have nonspecific ionic charge interactions with cell surfaces. Efficient transfection of cells by cationic complexes is, in part, contributed by adequate charge interactions. In addition, recent publications report that certain viruses have a partial positive charge around key subunits of viral proteins on the virus surface responsible for binding to and internalization through target cell surface receptors. Therefore, this partial positive charge is required for virus entry into the cell. Thus, maintenance of adequate positive charge on the surface of targeted liposome complexes is essential for optimal delivery into the cell. Different formulations of liposomes interact with cell surfaces via a variety of mechanisms. Two major pathways for interaction are by endocytosis or by direct fusion with the cell membrane. Preliminary data suggest that nucleic acids delivered *in vitro* and *in vivo* using complexes developed in our lab enter the cell by direct fusion (Fig. 6). Apparently, the bulk of the nucleic acids do not enter endosomes, and, therefore, far more nucleic acid enters the nucleus. Cell transfection by direct fusion produces orders of magnitude increased levels of gene expression and numbers of cells transfected versus cells transfected through the endocytic pathway.

We believe that maintenance of adequate positive charge on the surface of complexes is essential to drive cell entry by direct fusion. Therefore, we create targeted delivery of our complexes *in vivo* without

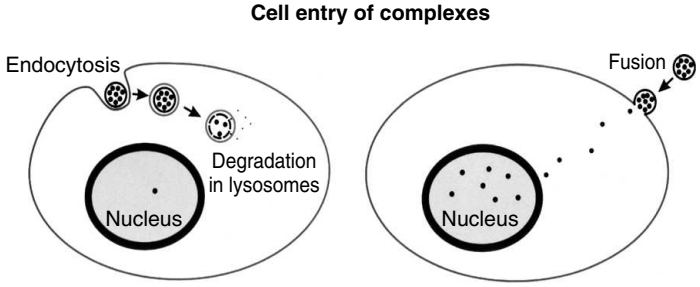

Fig. 6 Mechanisms for cell entry of nucleic acid–liposome complexes. Two major pathways for interaction are by endocytosis or by direct fusion with the cell membrane. Complexes that enter the cell by direct fusion allow delivery of more nucleic acids to the nucleus because the bulk of the nucleic acids do not enter endosomes.

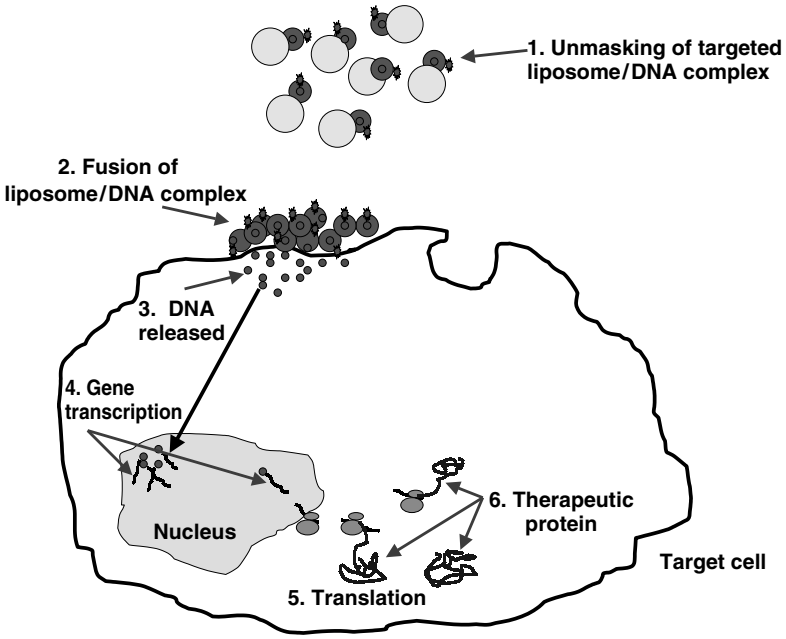

Fig. 7 Optimized strategy for delivery and gene expression in the target cell. Optimization of many steps is required to achieve targeted delivery, deshielding, fusion with the cell membrane, entry of nucleic acids into the cell and to the nucleus, and production of gene expression of a cDNA cloned in a plasmid.

the use of PEG. These ligand-coated complexes also reexpose the overall positive charge of the complexes as they approach the target cells. Through ionic interactions or covalent attachments, we have added monoclonal antibodies, Fab fragments, proteins, partial proteins, peptides, peptide mimetics, small molecules, and drugs to the surface of our complexes after mixing. These ligands efficiently bind to the target cell surface receptor, and maintain entry into the cell by direct fusion. Using novel methods for addition of ligands to the complexes for targeted delivery results in further increased gene expression in the target cells after transfection. Therefore, we design targeted liposomal delivery systems that retain predominant entry into cells by direct fusion versus the endocytic pathway. Figure 7 shows our optimized strategy to achieve targeted delivery, deshielding, fusion with the cell membrane, entry of nucleic acids into the cell and to the nucleus, and production of gene expression of a cDNA cloned in a plasmid.

7 Ligands Used for Targeted Delivery

Using liposomes that encapsulate nucleic acids, ligands can be coated onto the surface of the complexes formed (Fig. 8). We have added monoclonal antibodies, Fab fragments, proteins, partial proteins, peptides, peptide mimetics, small molecules, and drugs to the surface of the complexes after mixing. Ligands are chosen by their ability to efficiently bind to a

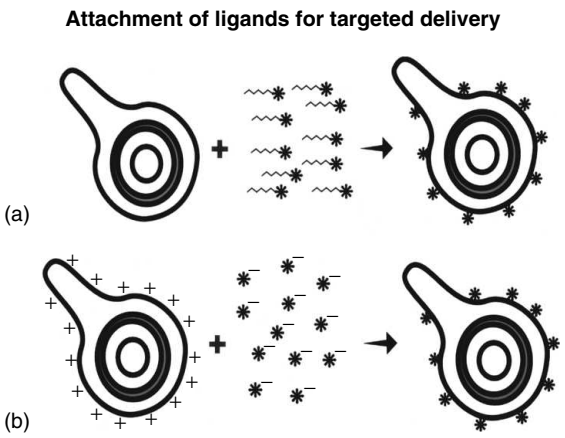

Fig. 8 Cross sections of extruded DOTAP:Chol-nucleic acid–liposome complexes (left) that are coated with ligands (right). Ligands are attached to the surface of preformed nucleic acid–liposome complexes by covalent attachments through ''linker lipids'' (a) or by ionic interactions (b).

target cell surface receptor while maintaining entry into the cell by direct fusion. Entry into the cell will be discussed further below. The ligands most useful for gene therapeutics in humans will be those that are smallest and possess high affinity for the target receptor. Nonviral systems are desirable because they can be repeatedly administered. Therefore, immune responses may be generated in animals or people upon repeated administration of complexes containing too much ligand or too large a ligand on the surface. These immune responses could cause the targeted therapeutics to be unsafe and/or ineffective for treatments in the clinic.

However, often the ''best ligand'' is not always available immediately. An investigator could also wait for years for the most appropriate ligand to be generated or produced in the amounts required for large experiments. Our experience shows that much useful information can be generated concerning targeting of a particular cell surface receptor of interest using the ''less-than-ideal ligand'' *in vitro* and *in vivo* in pilot experiments while creating the best ligand concurrently.

8 Attachment of Ligands

Generally, investigators attach ligands to PEG for incorporation into liposomes and other conjugates or for coating onto the surface of complexes after mixing. After extensive work with PEG in our lab, we have chosen or created alternative methods to use for the attachment of ligands, and have avoided the use of PEG due to its numerous disadvantages discussed above and below in this chapter.

Alternative strategies to the use of PEG include attachment of ligands through ionic interactions or by covalent attachment to ''linker lipids''. The ligands listed in the section above are generally negatively charged. Therefore, the ligands can simply be adsorbed onto the surface of complexes with encapsulated nucleic acids after mixing (Fig. 8b). Additional moieties can be added to the ligand to increase the amount of negative charge, and yet do not interfere with the ability of the modified ligand to efficiently bind to the appropriate cell surface receptor. For example, we used succinylated asialofetuin to target delivery of DNA–liposome complexes to the asialoglycoprotein receptor on

hepatocytes in the liver. The succinic acid amides provided greater negative charge to asialofetuin, and, therefore, bound to the surface of complexes more efficiently than asialofetuin alone. The amount used for adsorption onto the surface of complexes is ligand dependent. Titration studies must be performed to determine the optimal amount of ligand to coat onto the surface of complexes. Ultimately, *in vivo* transfection experiments must be performed to verify the optimal amount of ligand to use to provide delivery to the target cells and the highest levels of gene expression in these cells with no generation of an immune response.

Ligands or modified ligands containing reactive groups can be covalently attached to linker lipids (Fig. 8a). These ligand–lipid conjugates must be checked for optimal activity of the ligand to bind to its receptor. Furthermore, the covalent linkage must not be immunogenic in animals or people after repeated administration. Ligand–lipid conjugates can be spontaneously inserted into the outside membrane of complexes in which the nucleic acids are encapsulated within liposomes (Figure 8b). The amount of ligand–lipid used for insertion into the surface of complexes is also ligand dependent. Titration studies must be performed to determine the optimal amount of ligand–lipid to insert into the surface of complexes. Again, *in vivo* transfection experiments must be performed to verify the optimal amount of ligand–lipid to use to provide delivery to the target cells and the highest levels of gene expression in these cells with no generation of an immune response.

Using the alternative approaches described above, we have produced complexes that provide delivery of nucleic acids to target cells. Furthermore, the gene expression in the target cells using the targeted complexes is higher than that using the ''generic'' extruded DOTAP:Chol complexes.

9
Serum Stability of Optimized Nucleic Acid–Liposome Complexes for Use *in vivo*

Serum stability of cationic complexes is complicated and cannot be assessed by simply performing studies at a random concentration of serum. Figure 9 shows results from serum stability studies of DNA–liposome complexes that have been optimized in our laboratory for systemic delivery. Serum stability of these complexes was studied at 37 °C out to 24 h at concentrations of serum ranging from 0 to 100%. Two different serum stability assays were performed. The first assay measured the OD400 of BIV DOTAP:Chol–DNA–liposome complexes added into tubes containing a different concentration of serum in each tube, ranging from 0 to 100%. The tubes were incubated at 37 °C, and small aliquots from each tube were removed at various time points out to 24 h. The OD400 of each aliquot was measured on a spectrophotometer calibrated to accurately measure turbidity. Previous work in our laboratory demonstrated that the OD400 predicted both the stability of the complexes and the transfection efficiency results obtained for multiple organs after intravenous injections. Percent stability for this assay is defined as the transfection efficiency that is obtained at a particular OD400 of the complexes used for intravenous injections. Therefore, this assay is rigorous because slight declines in OD400 of these complexes result in obtaining

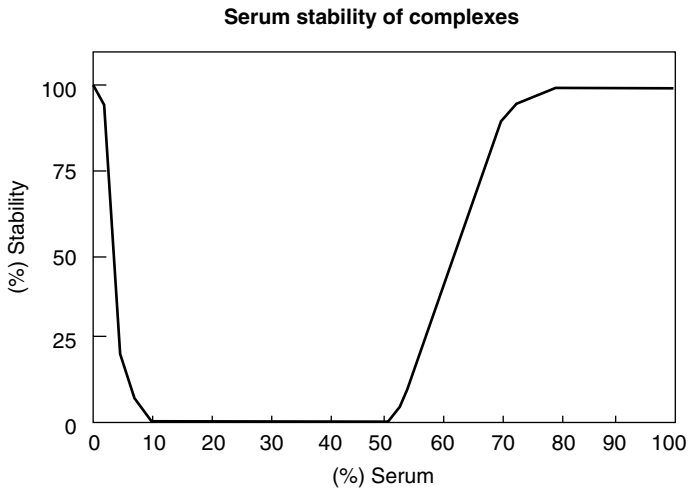

Fig. 9 Serum stability profile for DNA–liposome complexes optimized for systemic delivery. Serum stability of these complexes was studied at 37 °C out to 24 h at concentrations of serum ranging from 0 to 100%. Serum stability at the highest concentrations of serum, about 70 to 100%, that are physiological concentrations of serum found in the bloodstream is required.

no transfection *in vivo*. Declines in the OD400 also measure precipitation of the complexes.

A second assay was performed to support the results obtained from the OD400 measurements described above. A different concentration of serum, ranging from 0 to 100%, was placed into each well of a 96-well micro titer dish. BIV DOTAP:Chol–DNA–liposome complexes were added to the serum in the wells, and the plate was incubated at 37 °C. The plate was removed at various time points out to 24 h and complexes in the wells were observed under the microscope. Precipitation of complexes in the wells was assessed. 100% stability was set at no precipitation observed. Results from this assay were compared with those obtained in the first assay. 100% stability of complexes was set at no decline of OD400 in assay #1 and no observed precipitation in assay #2 at each % serum concentration, and the results were plotted (Fig. 9).

The results showed serum stability at the highest concentrations of serum, about 70 to 100%, that are physiological concentrations of serum found in the bloodstream. In addition, these complexes were also stable in no or low concentrations of serum. The complexes were unstable at 10 to 50% serum, perhaps due to salt bridging. Therefore, *in vitro* optimization of serum stability for formulations of cationic complexes must be performed over a broad range of serum concentration to be useful for applications *in vivo*.

10 Optimized Half-life in the Circulation

As stated above, the extruded BIV DOTAP:Chol–nucleic acid complexes are large enough so that they are not cleared

rapidly by Kupffer cells in the liver and yet extravasate across tight barriers and diffuse through the target organ efficiently. Further addition of ligands to the surface of extruded BIV DOTAP:Chol–nucleic acid complexes does not significantly increase the mean particle size. Extravasation and penetration through the target organ and gene expression produced after transfection are not diminished. These modified formulations are positively charged and deliver nucleic acids efficiently into cells *in vitro* and *in vivo*. Because extruded BIV DOTAP:Chol–nucleic acid complexes with or without ligands have a 5-h half-life in the circulation, these complexes do not accumulate in the skin, hands, or feet. Extended half-life in the circulation is provided primarily by the formulation, preparation method, injection of optimal colloidal suspensions, and optimal nucleic acid:lipid ratio used for mixing complexes, serum stability, and size (200 to 450 nm). Therefore, these BIVs are ideal for use in the development of effective, targeted nonviral delivery systems that clearly require encapsulation of nucleic acids.

11
Broad Biodistribution of Optimized Liposome Formulations

Our ''generic'' BIV nucleic acid–liposome formulation transfects many organs and tissues efficiently after intravenous injection, and has demonstrated efficacy in animal models for lung cancer, pancreatic cancer, breast cancer, Hepatitis B and C (Clawson and Templeton, unpublished data), and cardiovascular diseases. Therefore, optimization of the morphology of the complexes, the lipids used, flexibility of the liposomes and complexes, colloidal suspension, overall charge, serum stability, and half-life in circulation allows for efficient delivery and gene expression in many organs and tissues other than the lung. Apparently, these extruded DOTAP:Chol BIV nucleic acid–liposome complexes can overcome the tendency to be adsorbed only by the endothelial cells lining the circulation surrounding the lungs described by other investigators. However, as discussed above and below, we can further direct delivery to specific target tissues or cells by our targeted delivery strategies in combination with reversible masking used to bypass nonspecific transfection.

12
Optimization of Targeted Delivery

Much effort has been made to specifically deliver nucleic acid–liposome complexes to target organs, tissues, and/or cells. Ligands that bind to cell surface receptors are usually attached to PEG and then attached to the cationic or anionic delivery vehicle. Owing to the shielding of the positive charge of cationic complexes by PEG, delivery to the specific cell surface receptor can be accomplished by only a small fraction of complexes injected systemically. Furthermore, delivery of PEGylated complexes into the cell occurs predominantly through the endocytic pathway, and subsequent degradation of the bulk of the nucleic acid occurs in the lysosomes. Thus, gene expression is generally lower in the target cell than when using the nonspecific delivery of highly efficient cationic complexes.

As discussed above, the vast majority of the injected PEGylated complexes bypasses the target cell. Apparently, the PEGylated complexes cannot utilize critical charge interactions for optimal transfection into cells by direct fusion. Inability to expose positive charge on the surface of

optimized complexes results in the transfection of fewer cells. PEGylation was first used to increase the half-life of complexes in the circulation and to avoid uptake in the lung. However, this technology also destroys the ability to efficiently transfect cells. We were able to increase the half-life in circulation of BIVs to 5 h without the use of PEG. Because the extended half-life of BIVs is not too long, this delivery system does not result in the accumulation of complexes in nontarget tissues that circulate for one to three days. Some investigators have now reported targeted delivery that produces increased gene expression in the target cell over their nontargeted complexes. However, these nontargeted and targeted delivery systems are inefficient compared to efficient delivery systems such as the BIVs.

In using the extruded BIV DOTAP:Chol–nucleic acid:liposome complexes, we produced an optimal half-life in the circulation without the use of PEG. Extended half-life was produced primarily by the formulation, preparation method, injection of optimal colloidal suspensions, serum stability, and optimal nucleic acid:lipid ratio used for mixing complexes, and size (200 to 450 nm). Furthermore, we avoided uptake in the lungs using the negative charge of the ligands and ''shielding/deshielding compounds'' that can be added to the complexes used for targeting just prior to injection or administration *in vivo*. Our strategy to bypass nonspecific transfection is called *reversible masking*. Addition of ligands using the novel approaches that we developed, adequate overall positive charge on the surface of complexes is preserved. In summary, we achieve optimal circulation time of the complexes, reach and deliver to the target organ, avoid uptake in nontarget tissues, and efficiently interact with the cell surface to produce optimal transfection.

13
Efficient Dissemination Throughout Target Tissues and Migration Across Tight Barriers

A primary goal for efficient *in vivo* delivery is to achieve extravasation into and penetration throughout the target organ/tissue ideally by noninvasive systemic administration. Without these events, therapeutic efficacy is highly compromised for any treatment, including gene and drug therapies. Achieving this goal is difficult because of the many tight barriers that exist in animals and people. Furthermore, many of these barriers become tighter in the transition from neonates to becoming adults. Penetration throughout an entire tumor is further hindered because of the increased interstitial pressure within most tumors. We believe that nonviral systems can play a pivotal role in achieving target organ extravasation and penetration needed to treat or cure certain diseases. Our preliminary studies have shown that extruded BIV DOTAP:Chol–nucleic acid:liposome complexes can extravasate across tight barriers and penetrate evenly throughout entire target organs, and viral vectors cannot cross identical barriers. These barriers include the endothelial cell barrier in a normal mouse, the posterior blood retinal barrier in adult mouse eyes, complete and even diffusion throughout large tumors, and penetration through several tight layers of smooth muscle cells in the arteries of pigs. Diffusion throughout large tumors was measured by expression of ß-galactosidase or the proapoptotic gene *p*53 in about half of the p53-null tumor cells after a single injection of BIV DOTAP:Chol – DNA–liposome

complexes into the center of a tumor. Transfected cells were evenly spread throughout the tumors. Tumors injected with complexes encapsulating plasmid DNA encoding p53 showed apoptosis in almost all of the tumor cells by TUNEL staining. Tumor cells expressing p53 mediate a bystander effect on neighboring cells perhaps due to upregulation by Fas ligand that causes nontransfected tumor cells to undergo apoptosis. Currently, we are investigating the mechanisms used by extruded DOTAP:Chol–nucleic acid:liposome complexes to cross barriers and penetrate throughout target organs. By knowing more about these mechanisms, we hope to develop more robust nonviral gene therapeutics.

14
Optimization of Plasmids for *in vivo* Gene Expression

Delivery of DNA and subsequent gene expression may be poorly correlated. Investigators may focus solely on the delivery formulation as the source of poor gene expression. In many cases, however, the delivery of DNA into the nucleus of a particular cell type may be efficient, although little or no gene expression is achieved. The causes of poor gene expression can be numerous. The following issues should be considered independent of the delivery formulation, including suboptimal promoter-enhancers in the plasmid, poor preparation of plasmid DNA, and insensitive detection of gene expression.

Plasmid expression cassettes typically have not been optimized for animal studies. For example, many plasmids lack a full-length CMV promoter-enhancer. Over one hundred variations of the CMV promoter-enhancer exist, and some variations produce greatly reduced or no gene expression in certain cell types. Even commercially available plasmids contain suboptimal CMV promoters-enhancers, although these plasmids are advertised for use in animals. Furthermore, upon checking the company data for these plasmids, one would discover that these plasmids have never been tested in animals and have been tested in only one or two cultured cell lines. Conversely, plasmids that have been optimized for overall efficiency in animals may not be best for transfection of certain cell types *in vitro* or *in vivo*. For example, many investigators have shown that optimal CMV promoters-enhancers produce gene expression at levels several orders of magnitude less in certain cell types. In addition, one cannot assume that a CMV promoter that expresses well within the context of a viral vector, such as adenovirus, will function as well in a plasmid-based transfection system for the same cell context. Virus proteins produced by the viral vector are required for producing high levels of mRNA by the CMV promoter in specific cell nuclei.

Ideally, investigators design custom promoter-enhancer chimeras that produce the highest levels of gene expression in their target cells of interest. Recently, we designed a systematic approach for customizing plasmids used for breast cancer gene therapy using expression profiling. Gene therapy clinical trials for cancer frequently produce inconsistent results. We believe that some of this variability could result from differences in transcriptional regulation that limit expression of therapeutic genes in specific cancers. Our systemic liposomal delivery of a nonviral plasmid DNA showed efficacy in animal models for several cancers. However, we

observed large differences in the levels of gene expression from a CMV promoter-enhancer between lung and breast cancers. To optimize gene expression in breast cancer cells *in vitro* and *in vivo*, we created a new promoter-enhancer chimera to regulate gene expression. Serial analyses of gene expression (SAGE) data from a panel of breast carcinomas and normal breast cells predicted promoters that are highly active in breast cancers, for example, the glyceraldehyde 3-phosphate dehydrogenase (GAPDH) promoter. Furthermore, GAPDH is upregulated by hypoxia, which is common in tumors. We added the GAPDH promoter, including the hypoxia enhancer sequences, to our *in vivo* gene expression plasmid. The novel CMV-GAPDH promoter-enhancer showed up to 70-fold increased gene expression in breast tumors compared to the optimized CMV promoter-enhancer alone. No significant increase in gene expression was observed in other tissues. These data demonstrate tissue-specific effects on gene expression after nonviral delivery, and suggest that gene delivery systems may require plasmid modifications for the treatment of different tumor types. Furthermore, expression profiling can facilitate the design of optimal expression plasmids for use in specific cancers.

Several reviews have stated that nonviral systems are intrinsically inefficient compared to viral systems. However, as discussed above, one must separate issues of the delivery vehicle versus the plasmid that is delivered. Case in point, we have shown that our extruded liposomes optimized for systemic delivery could outcompete delivery using a lentivirus. For example, we have compared SIVmac239, a highly noninfectious virus, with nonviral delivery of SIVmac239 DNA complexed to BIVs in adult rhesus macaques after injection into the saphenous vein of the leg. Our data showed that the monkeys injected with SIV DNA encapsulated in DOTAP:Chol BIVs were infected four days postinjection, and high levels of infection were produced in these monkeys at 14 days postinjection. Furthermore, higher levels of SIV RNA in the blood were produced using our BIV liposomes for delivery versus that using the SIV virus. CD4 counts were measured before and after injections. CD4 levels dropped in all monkeys to the lowest levels ever detected in the macaques in any experiment by 28 days postinjection, the first time point at which these counts were measured postinjection. All monkeys had clinical SIV infections and lost significant weight by day 28. These results were surprising because SIVmac239 is not highly infectious, and monkeys become sick with SIV infection only after several months or years postinjection with SIVmac239 virus. Therefore, we were able to induce SIV infection faster using our nonviral delivery of SIV plasmid DNA. In this case, we delivered a replication-competent plasmid so that gene expression increased over time posttransfection. Our delivery system was highly efficient and exceeded that of the lentivirus. The critical feature in this nonviral experiment was the plasmid DNA that was delivered.

Plasmids can be engineered to provide for specific or long-term gene expression, replication, or integration. Persistence elements, such as the inverted terminal repeats from adenovirus or adeno-associated virus, have been added to plasmids to prolong gene expression *in vitro* and *in vivo*. Apparently, these elements bind to the nuclear matrix thereby retaining the plasmid in cell nuclei. For regulated gene expression, many different inducible promoters are used that promote expression only in the presence of a positive regulator or in

the absence of a negative regulator. Tissue specific promoters have been used for the production of gene expression exclusively in the target cells. As discussed in the previous paragraph, replication-competent plasmids or plasmids containing sequences for autonomous replication can be included that provide prolonged gene expression. Other plasmid-based strategies produce site-specific integration or homologous recombination within the host cell genome. Integration of a cDNA into a specific "silent site" in the genome could provide long-term gene expression without disruption of normal cellular functions. Homologous recombination could correct genetic mutations upon integration of wild-type sequences that replace mutations in the genome. Plasmids that contain fewer bacterial sequences and that produce high yield upon growth in *Escherichia coli* are also desirable.

15 Optimization of Plasmid DNA Preparations

The transfection quality of plasmid DNA is dependent on the preparation protocol and training of the person preparing the DNA. For example, we performed a blinded study asking three people to make DNA preparations of the same plasmid from the same box of a Qiagen Endo-Free Plasmid Preparation kit. One person then mixed all of the DNA–liposome complexes on the same morning using a single vial of liposomes. One person performed all tail vein injections, harvesting of tissues, preparation of extracts from tissues, and reporter gene assays on the tissue extracts. *In vivo* gene expression differed 30-fold among these three plasmid DNA preparations.

One source for this variability is that optimized methods to detect and remove contaminants from plasmid DNA preparations have not been available. We have identified large amounts of contaminants that exist in laboratory and clinical grade preparations of plasmid DNA. These contaminants copurify with DNA by anion exchange chromatography and by cesium chloride density gradient centrifugation. Endotoxin removal does not remove these contaminants. HPLC cannot detect these contaminants. Therefore, we developed three proprietary methods for the detection of these contaminants in plasmid DNA preparations. We can now make clinical grade good manufacturing practices (GMP) DNA that does not contain these contaminants. To provide the greatest efficacy and levels of safety, these contaminants must be assessed and removed from plasmid DNA preparations. These contaminants belong to a class of molecules known to inhibit both DNA and RNA polymerase activities. Therefore, gene expression posttransfection can be increased by orders of magnitude if these contaminants are removed from DNA preparations. The presence of these contaminants in DNA also precludes high dose delivery of DNA–liposome complexes intravenously. Our group and other investigators have shown that intravenous injections of high doses of improved liposomes alone cause no adverse effects in small and large animals.

Some investigators have removed the majority of CpG sequences from their plasmids and report reduced toxicity after intravenous injections of cationic liposomes complexed to these plasmids. However, only low doses containing up to 16.5 μg of DNA per injection into each mouse were shown to reduce toxicity. Therefore, no significant dose response to CpG

motifs in plasmid DNA was demonstrated. To achieve efficacy for cancer metastases, particularly in mice bearing aggressive tumors, most investigators are interested in injecting higher doses in the range of 50 to 150 µg of DNA per mouse. Therefore, removal of CpG sequences from plasmid-based gene therapy vectors will not be useful for these applications because no difference in toxicity was shown after intravenous injections of these higher doses of plasmids, with or without reduced CpG sequences, complexed to liposomes. Therefore, we believe that removal of the other contaminants in current DNA preparations, discussed above, is the major block to the safe intravenous injection of high doses of DNA–liposome complexes.

16 Detection of Gene Expression

Thought should also be given to choosing the most sensitive detection method for every application of nonviral delivery rather than using the method that seems most simple. For example, detection of ß-galactosidase expression is far more sensitive than that for the green fluorescent protein (GFP). Specifically, 500 molecules of ß-galactosidase (ß-gal) per cell are required for detection using X-gal staining. Whereas, about one million molecules of GFP per cell are required for direct detection. Furthermore, detection of GFP may be impossible if the fluorescence background of the target cell or tissue is too high. Detection of chloramphenicol acetyltransferase (CAT) is extremely sensitive with little or no background detected in untransfected cells. Often, assays for CAT expression can provide more useful information than using ß-gal or GFP as reporter genes.

Few molecules of luciferase in a cell can be detected by luminescence assays of cell or tissue extracts posttransfection. The sensitivity of these assays is highly dependent on the type of instrument used to measure luminescence. However, luciferase results may not predict the therapeutic potential of a nonviral delivery system. For example, if several hundred or thousand molecules per cell of a therapeutic gene are required to produce efficacy for a certain disease, then production of only few molecules will not be adequate. If only few molecules of luciferase are produced in the target cell using a specific nonviral delivery system, then the investigator may be misled in using this system for therapeutic applications.

Furthermore, noninvasive detection of luciferase expression *in vivo* is not as sensitive as luminescence assays of cell or tissue extracts posttransfection. Recently, some colleagues of mine tried cooled charge coupled device (CCD) camera imaging on live mice after intravenous injection of other cationic liposomes complexed to plasmid DNA encoding luciferase, and they were not able to detect any transfection. However, these liposomal delivery systems had been used to detect luciferase by luminescence assays of organ extracts. My colleagues detected luciferase expression by CCD imaging after intravenous injections of BIV DOTAP:Chol-luciferase DNA–liposome complexes. Using the same CCD imaging system following intravenous injections of PEI-DNA complexes, extremely poor transfection efficiency was observed in all tissues. Because the luciferase protein is short-lived, maximal expression was detected at 5 h posttransfection. Whereas, detection of HSV-TK gene expression using microPET imaging in the same mice was highest at 24 h posttransfection. In contrast to

luciferase, the CAT protein accumulates over time, and, therefore, the investigator is not restricted to a narrow time frame for assaying gene expression. Furthermore, detection of CAT seems to be more sensitive than CCD imaging of luciferase following intravenous injections of DNA–liposome complexes. However, the animals must be sacrificed in order to perform CAT assays on tissue or organ extracts. In summary, further work is still needed to develop *in vivo* detection systems that have high sensitivity and low background.

17 Optimization of Dose and Frequency of Administration

To establish the maximal efficacy for the treatment of certain diseases or for the creation of robust vaccines, injections, or administrations of the nonviral gene therapeutic, and so on via different routes may be required. For particular treatments, one should not assume that one delivery route is superior to others without performing the appropriate animal experiments. In addition, people with the appropriate expertise should perform the injections and administrations. In our experience, only a minority of people who claim expertise in performing tail vein injections can actually perform optimal injections.

The optimal dose should be determined for each therapeutic gene or other nucleic acid that is administered. The investigator should not assume that the highest tolerable dose is optimal for producing maximal efficacy. The optimal administration schedule should also be determined for each therapeutic gene or other nucleic acid. To progress faster, some investigators have simply used the same administration schedule that they used for chemotherapeutics, for example. The investigator should perform *in vivo* experiments to determine when gene expression and/or efficacy drops significantly. Most likely, readministration of the nonviral gene therapeutic is not necessary until this drop occurs. Loss of the therapeutic gene product will vary with the half-life of the protein produced. Therefore, if a therapeutic protein has a longer half-life, then the gene therapy could be administered less frequently.

18 Summary

Overcoming some hurdles remains in the broad application of nonviral delivery; however, we are confident that we will successfully accomplish the remaining challenges soon. Furthermore, we predict that eventually the majority of gene therapies will utilize artificial reagents that can be standardized and regulated as drugs rather than biologics. We will continue to incorporate the molecular mechanisms of viral delivery that produce efficient delivery to cells into artificial systems. Therefore, the artificial systems, including liposomal delivery vehicles, will be further engineered to mimic the most beneficial parts of the viral delivery systems while circumventing their limitations. We will also maintain the numerous benefits of the liposomal delivery systems discussed in this chapter.

Keywords

Aflatoxins
A family of natural toxins produced by *Aspergillus* species, inducing mutations in animals and involved in liver cancer development.

Axin1
The gene encoding a protein that facilitates the degradation of oncogenic β-catenin protein that is inactivated by mutation in liver cancers.

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Volume 7
Edited by Robert A. Meyers.

ISBN: 3-527-30549-1

β-catenin
A proto-oncogene when mutated contributes to the development of liver cancer.

Cyclin D1
A gene-encoding cyclin partner of cyclin-dependent kinase 4 that is amplified in liver cancers.

Hepatitis B Virus
A small DNA virus that infects hepatocytes in the liver, causing acute or chronic hepatitis.

Hepatitis C Virus
A small RNA virus infecting hepatocytes in the liver, causing acute or chronic hepatitis.

$P16^{INK4a}$
The gene encoding a protein that inhibits the activity of cyclin-dependent kinase 4 that is inactivated by *de novo* methylation in different cancers, including liver cancers.

p53
A tumor suppressor gene that is inactivated by mutation in different cancers including liver cancers.

Primary liver cancer is the fifth most common cancer worldwide. Hepatocellular carcinoma (HCC), which constitutes 80% of liver cancers, is linked etiologically to hepatitis B virus (HBV), hepatitis C virus (HCV), and aflatoxins. Hepatocellular carcinoma results from malignant transformation of hepatocytes and/or its progenitor cells. Viral factors appear to contribute to hepatocellular carcinogenesis nonspecifically by inducing chronic liver regeneration leading to cirrhosis, followed by HCC. Major cellular genes that are mutated in HCC are *β-catenin* and *Cyclin D1* oncogene, as well as *p53* and *axin1* tumor suppressor genes. *$P16^{INK4a}$*, another tumor suppressor gene is inactivated by promoter hypermethylation. These mutations affect p53, retinoblastoma, and wnt pathways in HCC, leading to a loss of proliferation control, escape from apoptosis and senescence, and probably, aberrant differentiation process.

1 Epidemiology of Liver Cancers and Hepatocellular Carcinoma

Primary liver cancer is a major public health problem, worldwide. It is the fifth most common cancer in the world, and third most common cause of cancer-related death. Hepatocellular carcinoma, cholangiocarcinoma, and hepatoblastoma are the main forms of cancer of the liver. However, the great majority (more than

80%) of primary liver tumors are HCCs. More than 500 000 new cases of HCC are diagnosed each year. Long considered as a disease of people living in Africa and Asia, HCC is now becoming a serious health threat in Europe and North America also because of its rising incidence.

Chronic infection with HBV, HCV, as well as naturally occurring aflatoxins were classified as carcinogenic to humans by International Agency for Cancer Research (IARC) working groups. These three etiologic factors constitute the majority of liver cancer risk factors in the world. Other risk factors for liver carcinomas are alcohol, nonviral cirrhosis, autoimmune chronic active hepatitis, and metabolic diseases, such as α-1-antitrypsin deficiency and hemochromatosis. Hepatitis B virus is the major etiology in Asia and Africa, whereas HCV appears to be more involved in HCCs occurring in Japan, Europe, and North America.

All major etiological factors of HCC have in common the ability to cause chronic liver disease leading to viral cirrhosis, which represents the single most common cause of these tumors with a contribution to over 80% of these cancers. The chronic process leading to cirrhosis with further development into HCC may take many years. Therefore, when analyzing the molecular etiology of HCC, it is often to dissociate viral from host-related contributions. Although involved as major causes, HBV and HCV differ from *bona fide* oncogenic viruses such as human papillomavirus 16 in their contributions to cancer. Their contribution to HCC appears to be rather nonspecific, mainly through the chronic liver regeneration process that they are known to be more directly involved in.

2
Molecular Biology of Hepatocellular Carcinoma

The liver is the largest internal organ that exhibits endocrine, exocrine, metabolic, and detoxification activities. Hepatocytes carry out the main functions of the liver and account for approximately 80% of all liver cells. Hepatocellular carcinoma is believed to originate from these mature cells, and/or from their progenitors. Therefore, a short overview of hepatogenesis and homeostasis of normal and diseased liver may be helpful for a better understanding of HCC biology.

2.1
Hepatogenesis and Homeostasis in the Adult Liver

Hepatogenesis is a process that consists of distinct developmental stages: competence, commitment, differentiation, and morphogenesis of hepatocytes. The liver develops from the ventral gut endoderm juxtaposing the developing heart. The entire embryonic endoderm is competent to adopt a hepatic fate and expresses the transcription factor HNF-3. Signals, including FGFs, released by cardiac mesoderm act on the underlying ventral endoderm of the foregut, inducing it to commit to a hepatic cell fate. In response to this, the prehepatic endoderm begins to express genes associated with a differentiated hepatocyte phenotype. At this stage of early development, these cells are called *hepatoblasts* or embryonic liver stem cells as they are at least bipotential, giving rise to both hepatocyte and bile epithelial cell lineages. The mechanisms controlling liver stem cell phenotype and the bipotential cell lineage commitment are mostly unknown. As far as the hepatocyte lineage is concerned,

expression of the full array of genes necessary for hepatocyte function requires the transcription factor HNF-4α. This differentiation step is followed by a period of rapid cell growth and morphogenesis that results in a functioning liver. Growth of the liver requires several transcription factors expressed in hepatocytes including NF-κB, c-Jun, and XBP-1.

The adult liver is estimated to be replaced by normal tissue renewal approximately once a year. This very slow process is maintained mainly by proliferation of differentiated hepatocytes. These hepatocytes are also able to restore the replacement of large volumes of liver tissue losses, following partial hepatectomy, for example, and during chronic liver diseases. However, under experimental conditions during which the proliferation of mature hepatocytes is suppressed, the liver mass can also be restored by adult liver cells, also called *oval* cells believed to reside in the liver. Furthermore, it has been shown that liver hepatocytes can also be derived from bone marrow cell populations in humans. Thus, the adult liver appears to be equipped with a powerful cell renewal system using mature hepatocytes, liver stem cells, or even bone marrow–derived stem cells.

2.2 Hepatocyte Regeneration During Chronic Liver Disease

The major etiological factors of HCC, namely, HBV and HCV may induce a chronic disease characterized by repeated inflammation, degeneration, and regeneration cycles in the liver. This chronic process is maintained by repetitive cycles of ''exposure, inflammation, necrosis/apoptosis and regenerative response''. After tens of years, the chronic hepatitis will lead to a cirrhosis stage, which is manifested by metabolic and replicative failure accompanied with the formation of fibrosis in the diseased liver. The HCC may arise at this stage from dysplastic nodules of hepatocytes without an overt stage of adenoma. The major limiting factors against the occurrence of malignant transformation are cell death and senescence. Therefore, HCC cells must acquire new abilities to escape from these limiting factors, namely, resistance to both apoptosis and senescence.

The process of inflammation in chronic liver disease creates a sustained state of oxidative stress. Reactive oxygen species can be generated during the inflammatory response to viral hepatitis or internally by the metabolic stress of hepatocytes. This oxidative stress is usually taken care of, at least initially, by antioxidant processes. Selenium is considered to play an indirect antioxidant role as an essential constituent of a selenoprotein, namely, glutathione peroxidase (Gpx), in elimination of cellular reactive oxygen species. Cytosolic or classical Gpx (Gpx-1) is considered as the most critical enzyme for the protective effects of selenium. It has recently been shown that selenium deficiency leads to apoptosis in hepatocyte-derived cells, due to oxidative stress. On the other hand, most HCC cells are tolerant to selenium deficiency and oxidative stress-inducing conditions. Thus, selenium deficiency in liver may confer growth advantage to malignant tumor cells, since they appear to adapt themselves to a selenium-deficient cellular environment.

Resistance to oxidative stress is probably one of the many ways in which malignant hepatocytes become resistant to apoptosis. Additional mechanisms involving the apoptotic machinery itself exist. Among

others, resistance to *Fas*-mediated apoptosis, changes in the expression of *bcl-2* family of genes, as well as *p53* gene mutations appear to confer apoptosis resistance to HCC cells.

2.3 Genetic and Epigenetic Changes in Hepatocellular Carcinoma

Hepatocellular cancers display many chromosomal changes (aneuploidies) such as polyploidy, loss of heterozygosity, allelic imbalance, amplifications as well as translocations. Aneuploidy is a general feature of solid tumors, so its occurrence in HCC is not surprising. In addition, it is well established that HBV DNA integrates into the host genome causing many chromosomal rearrangements. It is expected that the chromosomal regions that undergo tumor-specific changes harbor critical genes involved in carcinogenesis.

Historically, the oncogenes were first discovered as transforming viral genes. It was later shown that most viral oncogenes are activated forms or homologs of cellular proto-oncogenes involved in positive regulation of cell proliferation. Cellular proto-oncogenes can also be activated by somatic or even germ-line mutations, in the absence of viral participation. There are several cellular oncogenes (β-catenin, cyclins, etc.), which are considered as oncogenic in human hepatocellular carcinogenesis. There are also suspected viral oncogenes of HBV (mainly *X* gene) and hepatitis C virus (mainly core gene), which may contribute to hepatocellular cancer development. However, despite endless efforts, the true oncogenic role of these viral genes in human hepatocellular carcinogenesis is still a matter of debate (Table 1).

Tab. 1 The status of oncogenes and tumor suppressor genes in hepatocellular cancers.

Gene	*Mutation (%)*	*Other alterations*
p53	28	HBx interaction

Source: This table was constructed by the modification of a table presented in Ozturk M., Cetin-Atalay R. (2003) Biology of Hepatocellular Cancer, in: Rustgi A. (Ed.) *Gastrointestinal Cancers: Biology, Diagnosis and Therapy*, 2nd edition, Lippincott-Raven Press, New York. Ozturk & Cetin-Atalay, 2003, to include recent data for additional alterations.

Tumor suppressor genes (or anti-oncogenes) are another group of cellular genes whose inactivation contributes to carcinogenesis. These genes, discovered much later than oncogenes, appear to be the most frequently mutated genes in different cancers, including hepatocellular cancers. To date, many tumor suppressor genes including *p53*, *mannose-6-phosphate/insulin-like factor 2 receptor* (*M6P/IGF2R*), *retinoblastoma* (*RB1*), $p16^{INK4A}$, *adenomatosis polyposis coli* (*APC*), *axin* (*axin1*), and *BRCA2* are known to be mutated in hepatocellular cancers (Table 1).

The list of hepatocellular cancer-associated oncogenes and tumor suppressor genes will probably grow over the coming years to include many more genes. There are at least two reasons to explain the high number of altered genes in HCC. Firstly, solid tumors in the adult may need the accumulation of many genetic alterations before they become clinically detectable. Indeed, the well-known ''latent period'' between the first exposure to an etiological agent (i.e. infection with HBV) and the development of HCC is in favor of such a hypothesis. Secondly, the multiplicity of genetic alterations in HCC may indicate that different etiological factors affect different sets of target genes in hepatocytes. This etiologically defined genetic heterogeneity of HCC results in a phenotypic heterogeneity of these tumors.

Here, we will review major oncogenes and tumor suppressor genes involved in HCC development.

2.3.1 Major Oncogenes

***β-catenin* (*CTNNB1*) gene** This gene encodes a pivotal component of the *Wnt* signaling pathway, which controls cell fate decisions during animal development. Inappropriate deregulation of this pathway leads to cancer in a number of tissues. The stability of β-catenin protein in the cytoplasm is low in unstimulated cells because of proteasome-mediated degradation by a protein complex, which consists of Axin, Adenomatosis polyposis coli (APC), and glycogen synthase kinase 3β (GSK3β). Wnt signaling inhibits the kinase activity of the quaternary complex. As a consequence, β-catenin accumulates in the cytoplasm, translocates to the nucleus, and becomes a transcriptional coactivator of T cell factor (TCF), the ultimate nuclear target of Wnt signaling. The *β-catenin* gene has recently been identified as one of the most frequently mutated genes in both hepatocellular carcinomas and hepatoblastomas. Both missense mutations and in-frame deletions mostly affect only exon 3 of *β-catenin* gene. These mutations affect, as a rule, the N-terminal region of β-catenin protein, which carry serine/threonine phosphorylation motifs involved in ''marking'' of the protein for ubiquitin-mediated degradation. Reported frequencies of β-catenin mutations in human HCC vary between 13 and 41%. Nuclear accumulation of β-catenin was reported to occur in 35% of HCCs. This could be due to mutations on other genes involved in β-catenin degradation. *Axin* gene mutations were found in 5% of HCCs. We have recently reported that, p53 mutations cause *in vitro* accumulation of β-catenin. It appears that β-catenin mutations in HCCs are as frequent as p53 mutation rates. Unlike p53, β-catenin mutations are also frequent (about 30%) in chemically induced rodent tumors. Childhood hepatoblastomas carry an even higher rate of β-catenin mutations. The reported frequencies vary between 48 and 89%, the overall rate being 58%.

Cyclin genes Cyclin genes comprise a gene family involved in the stepwise activation of cyclin-dependent kinases (CDK) during the cell cycle. Historically, the first cyclin gene known to be mutated in HCC is *CYCLIN A2* (*CCNA2*), which was identified in the integration site of HBV in a single tumor. Although this type of cyclin gene alteration has not been found in other tumors, this observation provided new clues about the implications of cyclin genes in HCC. Another cyclin known to be altered in HCC is the Cyclin D1 (*CCND1*; also called *PRAD1*) gene whose product forms active complexes with CDK4 enzyme during early G1 phase. The amplification of *Cyclin D* gene was observed in 10 to 13% of HCCs. *Cyclin D* gene amplification in HCC appears to be a late event, associated with more aggressive tumors.

2.3.2 Major Tumor Suppressor Genes

***P53* (*TP53*) gene** Many reports now indicate that the *p53* gene, which is located at chromosome 17p, is mutated in nearly one third of HCCs, worldwide. All of the reported p53 mutations in HCC are somatic. Therefore, germ-line mutations of p53 appear not to predispose to HCC. Both the frequency and the type of p53 mutations are different depending on geographical location and suspected etiology of these tumors. An HCC-specific codon 249 mutation (AGG->AGT leading to R249S), suspected to be induced by aflatoxins, was found in most HCCs from geographical areas with high incidence of HCC and with a high risk of exposure to aflatoxins. The codon 249 mutation is present in 36% of tumors from Africa and 32% of tumors from China. These two regions of the world are known for high incidence of HCC, where both HBV and aflatoxins are known to be the main etiological factors. In contrast, the codon 249 mutation is seen in less than 4% of HCCs from Japan, Europe, and North America, where HBV and HCV, but not aflatoxins are the main etiological factors. The overall frequency of codon 249 mutations in the world is 11%. Mutations affecting other codons of the *p53* gene are detected in HCC and their worldwide frequency is 18%. The frequency of all p53 mutations in HCC varies between 15% in Europe and 42% in China with a worldwide frequency of 27%. Thus, *p53* gene is mutated in about a third of HCCs, but only a third of these can be etiologically linked to a high risk of aflatoxin exposure. Therefore, p53 mutations can occur in HCC independent of aflatoxin risk, as well as HBV or HCV infection.

Cyclin-dependent kinase inhibitor genes Two closely located genes at chromosome 9p, namely, Cyclin-dependent Kinase (CDK) inhibitor 2a (*CDKN2A*, also called CDK4 inhibitor $p16^{INK4a}$ or MTS1) and cyclin-dependent kinase inhibitor 2b (*CDKN2B*, also called CDK4 inhibitor $p15^{INK4b}$ or *MTS2*) display genomic alterations in different human cancers. A number of studies demonstrated that the *CDKN2A* gene is strongly implicated in HCC. This gene codes for two alternatively spliced transcripts. One of the transcripts is for $p16^{CIP1KIP1}$ protein, an inhibitor of CDK4 and CDK6. The other transcript encodes for $p14^{ARF}$ protein, mouse homolog of which was shown to regulate wild-type p53 activity. More than 50% of HCCs display *de novo* methylation of *CDKN2A* gene, whereas its mutations are rare. It is known that *de novo* methylation is a mechanism involved in gene silencing. Therefore, HCC cells with methylated *CDKN2A*

gene are unable to express the gene, leading to the loss of a CDK inhibitor protein.

***Axin* (*AXIN1*) gene** *Axin* gene product is involved in the negative regulation of the *wnt* signaling. Like APC protein, the axin protein is required for active proteolytic degradation of β-catenin protein. *Axin* gene is mutated in about 5% of HCCs. The loss of the remaining *axin* gene allele was also demonstrated, suggesting that this gene acts as a tumor suppressor gene for HCC.

2.4 Molecular Mechanisms of Hepatocellular Carcinogenesis

The major genetic and epigenetic changes affecting mostly *p53*, *Retinoblastoma*, *p16*^{INK4a}, *β-catenin*, and *axin* genes allow us to link three major signaling pathways to malignant transformation of hepatocytes, namely, p53, retinoblastoma, and Wnt-β-catenin pathways. As shown in Fig. 1, these three pathways are involved in different processes that play key roles in malignant phenotype of not only HCC but also many other tumor types.

The p53 pathway, when it is active, controls three major cellular processes; namely, induction of apoptotic cell death, cell cycle arrest, and induction of senescence. Therefore, it is expected that p53 mutations that are observed at high frequency in HCC cells will lead to the inactivation of p53 pathway, together with a loss of p53-mediated apoptotic, antiproliferative, and antisenescence responses. Similarly, retinoblastoma pathway is involved in the control of cell cycle and permanent cell cycle arrest that is equivalent to senescence. The loss of p16^{INKa} expression in HCC may inactivate retinoblastoma pathway in these cells allowing them to escape from cell cycle control as well as from senescence.

The aberrant activation of Wnt-β-catenin pathway by mutations affecting β-catenin and Axin1 may confer new abilities to these cells such as autonomous proliferation ability, as well as cellular plasticity. Although hepatocellular effects of Wnt-β-catenin pathway activation are poorly

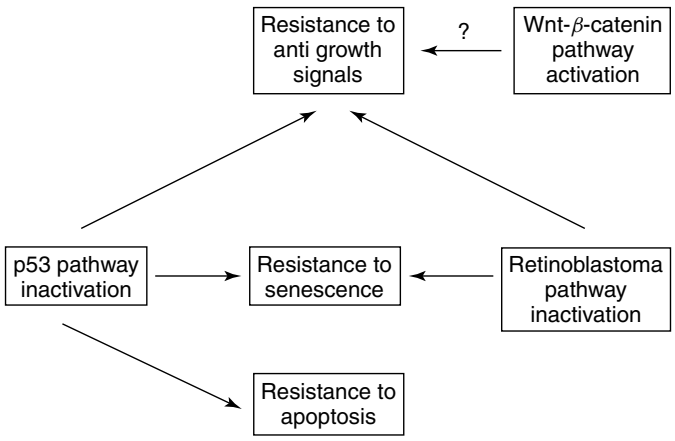

Fig. 1 Molecular mechanisms of hepatocellular carcinogenesis.

known, experimental data from colorectal cancers suggest that this activation may upregulate *Cyclin D1* and *c-myc* gene expression in these cells leading to an ability to proliferate even in the absence of mitogenic stimuli. In addition, activated Wnt-β-catenin pathway may confer HCC cells to gain a stem cell–like phenotype with the ability of unlimited self-renewal and generate progeny of differentiated cells that may count for an increased cell plasticity. With this regard, the origin of HCC is still under debate. According to the conventional theory, HCC results from the ''dedifferentiation'' of mature hepatocytes into a less differentiated state. A ''stem cell origin'' has been proposed as an alternative mechanism. According to this theory, HCC originates from ''oval'' cells displaying stem cell–like properties that are detected in the liver prior to the chemical induction of HCC in rats. Although ''oval'' cell-like structures have been described in association with different liver diseases, there is no convincing evidence for a direct contribution of liver stem cells to HCC in humans.

The molecular events leading to the development of HCC, whether it derives from a mature hepatocyte or a progenitor cell, are poorly understood. Future studies will probably focus on the role of Wnt-β-catenin pathway activation in HCC cells that will provide experimental evidence about whether such predictions are warranted.

Keywords

Genome
The complete nuclear DNA complement of an organism.

Genotype
The genetic make up of an individual, either at a specific locus, or considered across the whole genome.

Marker-assisted Selection (MAS)
Using DNA markers to aid the selection of animals of given genotype to achieve particular phenotypes.

Microsatellite Loci
A position in the genome where a short sequence (typically 2 or 3 bases long) is repeated several time in tandem.

Phenotype
The physical appearance or a measurable trait.

Quantitative trait loci (QTL)
A genetic locus that accounts for a proportion of the variation in a continuously distributed phenotype.

Selection
Choosing individuals with particular characteristics in order to improve the population.

Trait
A particular variable characteristic of individuals in a population.

Cattle have adapted to survive in a wide variety of environments, which has given rise to extensive diversity at the phenotypic and genetic level. Today, this diversity provides the opportunity for selective breeding and improvement of cattle for commercially desirable traits. Up to now, selection has been based on phenotype, focusing on the traits that are most easily measured. This approach has been successful, with

spectacular improvement in some traits, although there have also been associated penalties for other traits. However, intensive selection based on a limited number of phenotypes could reduce the diversity present in the population, which may have important implications for the success of future breeding objectives. In addition, selective improvement has been focused on a limited number of breeds, which are now used internationally, with the consequence that many of the genetically different breeds of cattle are being lost worldwide. To make the selection process more efficient, it is important to gain knowledge of the genes controlling particular traits and to understand the way that variation within these genes affects the traits. The first step toward identifying the trait genes has been to develop genetic and physical maps of the bovine genome. This has been achieved at an international level using several genome-mapping methods. The ultimate genome map, the bovine genome sequence, is now being determined. This genomic information is being used in specific cattle populations to identify, first the genetic location of genes controlling particular traits, then, starting from the genomic locations, to identify the genes themselves. Knowledge of the genes controlling complex traits, such as feed-conversion efficiency, health, fertility, and product quality, would allow these traits to be included in breeding objectives, with the potential for improved commercial viability, while safeguarding welfare and genetic diversity.

1 Introduction

There are more than 750 genetically different breeds of cattle worldwide, in addition to innumerable crossbred and undefined populations. This wealth of genetic diversity has enabled cattle to be raised in most environments inhabited by man; there are cattle populations adapted to survive in extremes of temperature, in arid areas and in the face of disease and parasite challenge. This environmental adaptation has, for the most part, been achieved by natural selection, insofar as those individuals that were best suited to their environment thrived and were therefore used to breed subsequent generations. The uses to which cattle have been put are equally as diverse as the environments in which they are kept. Cattle provide meat and milk for feed, are used for traction, and as a source of building materials, clothing, tallow, and glue, with numerous other uses found for the by-products of cattle production. The wealth of genetic diversity in cattle populations has provided the opportunity for selective breeding and improvement of cattle for particular uses. Today, selection has moved beyond the need for adaptation to environmental conditions to selecting on commercially desirable traits, at least in the developed world. Traditionally, breeding was carried out at the local level and those cattle that were selected for breeding were the ones that best fulfilled the local uses. More recently, cattle and semen have been moved around the world and selection has been carried out to achieve peak production under ideal, rather than local, conditions of management.

In modern breeding, the selection criteria adopted differ depending on the goals; for example, whether the end market is

beef or dairy production. However, in general, the traits used in the selection programs are those that are most readily accessible to measurement in commercial systems. Although, for example, feed efficiency is a very important factor in profitability for cattle production, this trait is often not taken into account because the trait is not readily recorded. Instead, selection is based on easily measured traits, in the case of dairy production on milk yield, protein, and fat content, and in the case of beef animals on growth rates and conformation. Over the past 40 years methods for breeding selection have improved, so that today selection of breeding sires is achieved by testing their progeny and applying sophisticated statistical methods, usually based on a ''best linear unbiased prediction'' (BLUP) model to calculate their relative genetic value for the desired traits. This approach is of greatest value in traits that are restricted by sex and age, for example, the prediction of the genetic merit of dairy-breed sires for milk traits. Application of this approach has given impressive results, for example, milk production from Holstein cows has doubled over the past 40 or so years. The progeny-testing approach has also resulted in significant improvements in beef-associated traits in the specialized beef breeds. Nevertheless, the gains achieved in a limited number of production traits come at the price of losses in other traits. The spectacular increases in milk yields achieved in the Holstein breed have been accompanied by decreased fertility and increased lameness. These losses are in part the result of an increased level of inbreeding, which is the inevitable penalty of a progeny-testing approach, as only a limited number of individuals can be tested in each generation. Along with losses in traits that are not under selection, the major problem associated with this approach, and associated with the consequent high level of inbreeding, is the potential concentration of deleterious recessive defects. As the level of inbreeding, defined by the inheritance of the same ancestral genes from both parents increases, the likelihood that an individual will inherit the same deleterious mutation from both parents also increases. This has been manifest in the elite Holstein dairy population by the appearance of genetic diseases such as DUMPS (deficiency of uridine mono-phosphate synthase), BLAD (bovine leukocyte adhesion deficiency), and most recently a bulldog calf syndrome.

In order to improve the process of genetic selection, it is important to develop a better knowledge of the genetic control of the various traits. The long-term goal is knowledge of the genes involved in particular traits, and an understanding of the variations within these genes, and how their products interact. This will ultimately allow the phenotype to be predicted from the genotype. In the shorter term, genetic maps and physical maps of the bovine genome are allowing markers for genes involved in particular traits and diseases to be localized, and in some cases, the genes themselves to be identified. The progress in unraveling the organization of the bovine genome is discussed below.

2 Domestication of Cattle

2.1 Origins of Domesticated Cattle

Analysis of both mitochondrial and nuclear DNA allows the relationships between cattle populations and their origins to be investigated. Domesticated cattle can

be classified into two groups on the basis of phenotype: *Bos indicus*, or Zebu cattle, are characterized by a hump at the shoulder, and *Bos taurus*, or Taurine cattle, which are humpless cattle. These two groups are sometimes referred to as subspecies, but they freely interbreed. *Bos indicus* cattle are better adapted to arid regions and crossbreeding between the two subspecies is often used to produce cattle with improved productivity in unfavorable dry regions. Comparison of mitochondrial "D-loop" DNA sequence confirms that the phenotypic distinction is reflected at the molecular level. The D-loop sequences fall into two groups, or clades, that coincide broadly with their geographic distribution. The exceptions are the African Zebu cattle, which have humps and phenotypically appear to be *B. indicus*, but have mitochondrial DNA that is typically taurine.

The distinction between *B. indicus* and *B. taurus* is also found by examining sequence diversity of nuclear DNA. Comparison of nuclear DNA is most commonly achieved by examining allelic variation at microsatellite loci (see Sect. 3.3). Construction of phylogenetic relationships between cattle using microsatellite data also produces two major clusters, which correspond with the indicus and taurine cattle. In the case of nuclear DNA the African Zebu cattle cluster with the taurine breeds, suggesting that they are hybrids. Examination of sequence variation on the Y chromosome and comparison with the maternally derived mitochondrial DNA allows the migration and dynamics of breeding to be examined, and confirms the introgression of male indicus genes into the original African taurine breeds.

The history of cattle domestication can be traced using both the mitochondrial and microsatellite data, and suggests that the indicus and taurine lineages diverged at least 22 000 years ago. The data also suggest two sites for domestication of cattle, both in the Middle East, from where domesticated cattle radiated out: the eastern domestication spreading to India, founding the indicus breeds, which were subsequently imported into east Africa, and the western site of domestication which spread via north Africa into Europe, founding the taurine breeds as shown in Fig. 1.

2.2 Cattle Breeds

Since domestication, cattle have been raised in a large variety of environmental conditions. It is therefore not surprising that extensive diversity began to appear both at the phenotypic and at the genetic level. Traditionally, breeding was carried out at a local level, often using a limited number of shared bulls. Originally cattle were selected primarily for survival, and fulfilled a range of production requirements, meat, milk, traction and so on, with equal emphasis. For the most part this is still the case, with the 70% of cattle raised in the developing world. The selection of individuals with particular characteristics suited to local environments, needs, and preferences, led to the emergence of distinctive groups of cattle with characteristic phenotypes. This phenotypic distinctiveness of groups of cattle was pursued by further selection, and later these groups were formalized into breeds, which were characterized by fixing particular features, typically colors or markings. With the establishment of breeds and the formation of societies to promote them, particularly in Europe and North America, there came the tendency for selection aimed at breeding cattle to suit particular production niches, such as breeds specializing in dairy or meat production. Some breeds that started

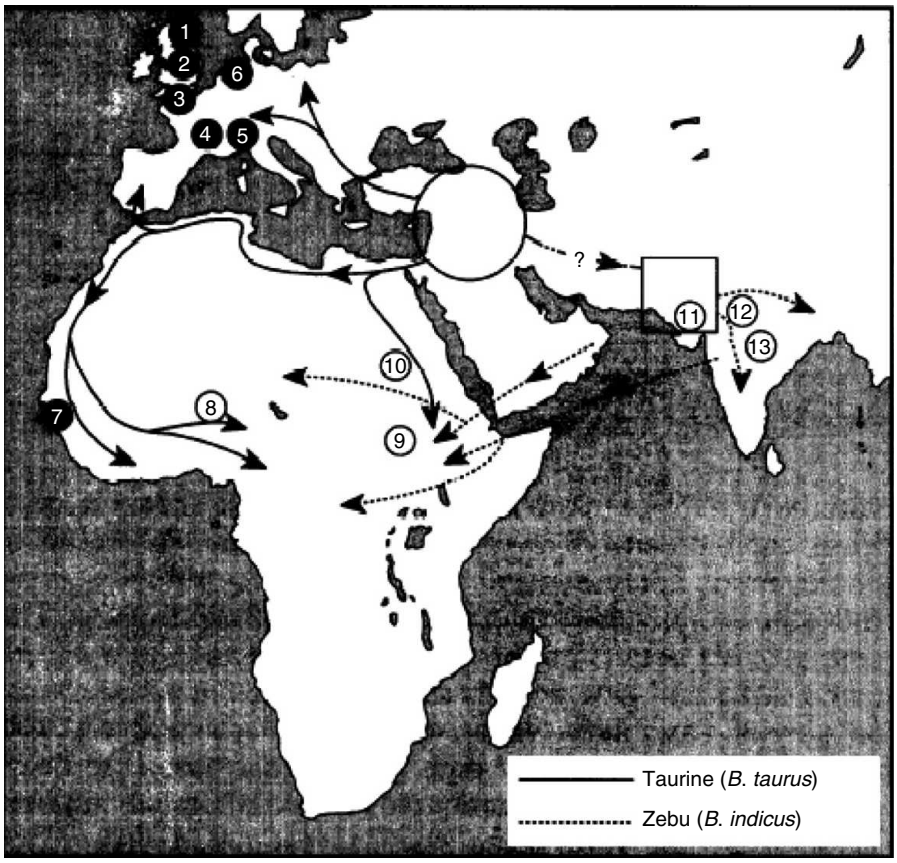

Fig. 1 Postulated migratory routes of cattle across western Asia, Africa, and Europe. Geographical origins of breed determined from mtDNA analysis of the following breeds (1) Aberdeen Angus, (2) Hereford, (3) Jersey, (4) Charolais, (5) Simmental (6) Friesian (7) N'Dama, (8) White Fulani, (9) Kenana, (10) Butana, (11) Tharparkar, (12) Sahiwal and 13 Hariana. *Bos taurus* breeds are illustrated by black symbols and *Bos indicus* breeds by open symbols (from Loftus, R.T., MacHugh, D.E., Bradley, D.G., Sharp, P.M., Cunningham, E.P. (1994) Evidence for two independent domestications of cattle, *Proc. Natl. Acad. Sci. U.S.A.* **91**, 2757–2761). Figure 1 (from Bradley et al. showing domestication origins).

with a dual function have more recently undergone strong selection for particular traits. The Friesian, which was used initially for both dairy and meat production, has become the leading dairy breed in the guise of the Holstein, in terms of quantity of milk produced. Modern dairy breeds produce far more milk than would be necessary to feed a calf, and often have trouble maintaining body weight during lactation. Conversely, selection of the meat-producing breeds has resulted in animals with little milk, in some cases insufficient milk for their calves, but with impressive muscular development, and in extreme cases are so muscle-bound that they have problems with locomotion. Thus, artificial selection has produced individuals that would not survive under natural selection.

The phenotypic distinctiveness of cattle breeds is also reflected at the genetic level. From the early 1960s through to the present day, biochemical markers, such as enzyme polymorphisms and later blood groups on the surface of red cells, detected using allo-antisera, has been used extensively by breed societies to verify the pedigrees of individuals and maintain the purity of their breeds. This biochemical information can also be used to track the genetic changes of breeds over this 40-year period, which coincides with the time during which the intensity of selection for increased productivity has also increased dramatically. Analysis of the blood-group data has shown that, in general, between-breed diversity is much larger than within-breed diversity. So individuals from the same breed cluster together. The phenotypic appearance of cattle breeds has changed in response to the intense selection that has been applied over the past 60 years. In addition, the livestock market has become international with semen, and to a lesser extent embryos, from many breeds being shipped all over the world. This has provided the opportunity for genetic divergence within the breeds as different selection criteria are applied in different regions; nevertheless, the genetic composition of breeds has remained relatively constant. Comparison of blood typing data over a 40-year period shows that although there has been some genetic drift, individuals remain more like their ancestors from the same breed, than individuals from other closely related or phenotypically similar breeds (see Fig. 2). Examination

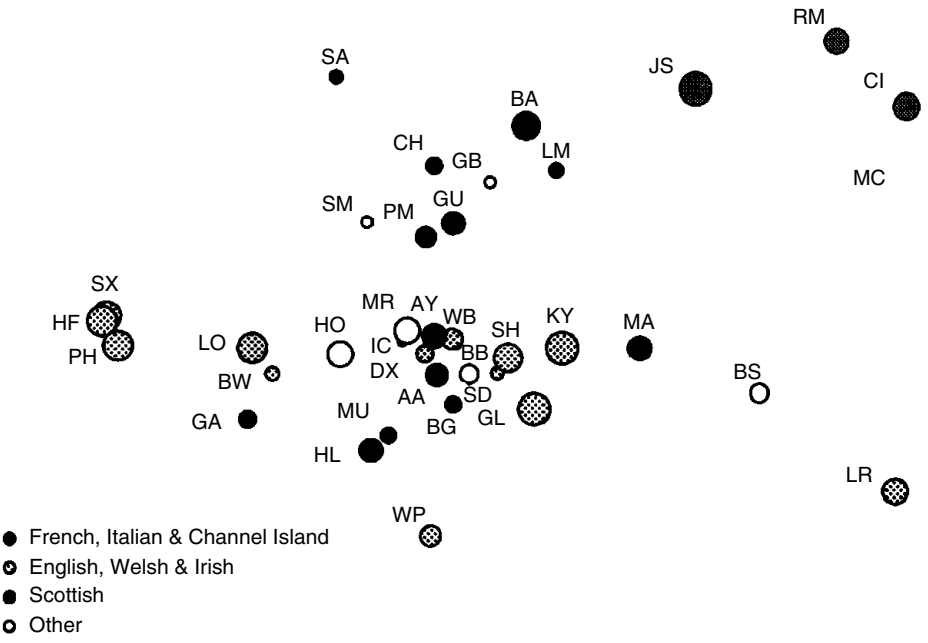

Fig. 2 Relationships between breeds based on a principal components analysis of differences between frequencies of red cell antigens (from Blott, S.C., Williams, J.L., Haley, C.S. (1998) Genetic relationships among European cattle breeds, *Anim. Genet.* **29**, 273–282). Figure 1 (from Bradley et al. showing domestication origins).

of individuals from different geographical locations reveals variations between the populations in different areas, most likely arising from a founder effect; however, the variation among individuals from a breed still remains smaller than the variation between breeds.

Other studies have used microsatellite loci to examine genetic diversity of cattle at the DNA level. A panel of 30 microstatellite loci has been selected, through a European Union network and have been adopted by the Food and Agriculture Organization of the United Nations for studies of diversity in cattle. This panel of markers is recommended for use in all studies of genetic diversity in cattle (see Table 1). The use of a common panel of markers should allow data to be integrated and compared between studies; this will allow changes in the genetic composition of breeds to be followed over time and genetic erosion to be monitored. The results from the microsatellite-based studies reflect the

same results as studies with biochemical markers, that is, for anonymous markers that are not subjected to selection: (1) breeds of cattle can be distinguished at the genetic level, and (2) within-breed variation is lower than between-breed variation. DNA markers are now replacing biochemical polymorphisms for pedigree verification, so a body of data is building up that could be used in the future to explore variations in the genetic diversity of cattle breeds.

The use of DNA markers has also been mooted for identifying the breed of an animal, or more appropriately in commercial terms the breed of origin of a meat sample. Unfortunately, although the analysis of DNA polymorphisms allows animals to be clustered by breed, there is overlap between the clusters. Therefore,

although it is statistically possible to assign individuals to breeds, there is likely to be considerable error in the result, at least with the number of markers currently used.

2.3 Conservation of Diversity

The introduction of artificial insemination (AI) in the more developed countries during the 1950s, coupled with improvement in management, has resulted in rapid progress in the improvement of cattle for simple production traits. This increasing use of AI meant that particular bulls with desirable characteristics became widely used in preference to local bulls. Consequently, where the economic environment supports high input agriculture, there has been a dramatic increase in milk yield and meat produced from the improved stock. The unfortunate consequence has been the reduction of genetic diversity, both within the selected breeds, as superior individuals have been used preferentially as breeding stock, and also through the replacement of traditional, less productive, breeds. In less developed and environmentally less favored areas, the use of the improved breeds presents a great cause for concern. Local breeds are usually adapted to survive in their local environments, for example, with increased tolerance of extremes in temperature or with the ability to survive and remain productive in the face of particular disease or parasite challenge. The inappropriate and/or unmanaged attempts to introduce improved breeds into some areas have met with disastrous consequences. In 1993, 112 of the 783 cattle breeds worldwide were at risk of extinction. One of the greatest risks is the replacement of local stock that are adapted for survival in the face of disease challenge with disease sensitive stock, in areas where standards and resources to provide extensive veterinary care are not available. It is important that genetic diversity is maintained, as this is the source of variation that will allow further selection. The first essential task is to record and monitor diversity across cattle populations. Screening genetic diversity using a limited number of DNA markers, such as the FAO panel discussed above, provides a crude measure of genetic diversity; however, this approach does not identify genes that are involved in specific adaptation or that control unique phenotypes. Thus, to preserve genetic diversity, much more extensive studies that consider the whole genome in more detail and that take into account variations in phenotypes are necessary. To this end, genome-mapping programs have the goal of identifying the genetic control of phenotypic variation.

3 Developing Maps of the Bovine Genome

The bovine genome is contained within 29 autosomes and the X and Y sex chromosomes, and consists of about 3 000 Mb of DNA. The autosomes are all acrocentric, that is, the centromere is at the end, while the sex chromosomes are sub-metacentric. Like most other mammalian genomes, the bovine genome is composed of less than 10% sequence that codes for proteins and about 50% of repetitive sequences. One major repetitive component is the bovine A-2 repeat, which has a core 115-bp element and comprises around 1.6% of the bovine genome. The second most common repeat element is the bovine SINE or bovine – B repeat, which is characterized by a 560-bp band seen by electrophoresis following digestion with the restriction enzyme *Pst*1,

the whole of this element is 3.1 kbp long and represents about 0.5% of the genome (see Fig. 3).

There has been considerable effort internationally to produce maps of the bovine genome driven for the most part by the objective of finding those genes that are involved in commercially important traits. Genomic maps can be compared between species to study the evolution of genomes and to reveal the organization and architecture of the DNA. This comparison will contribute to an understanding of the way the genome functions and the identification of those features that are important and that should be subjected to further study. There are several types of genomic map, which are either physical, or genetic. Physical maps can either be based on the localization of

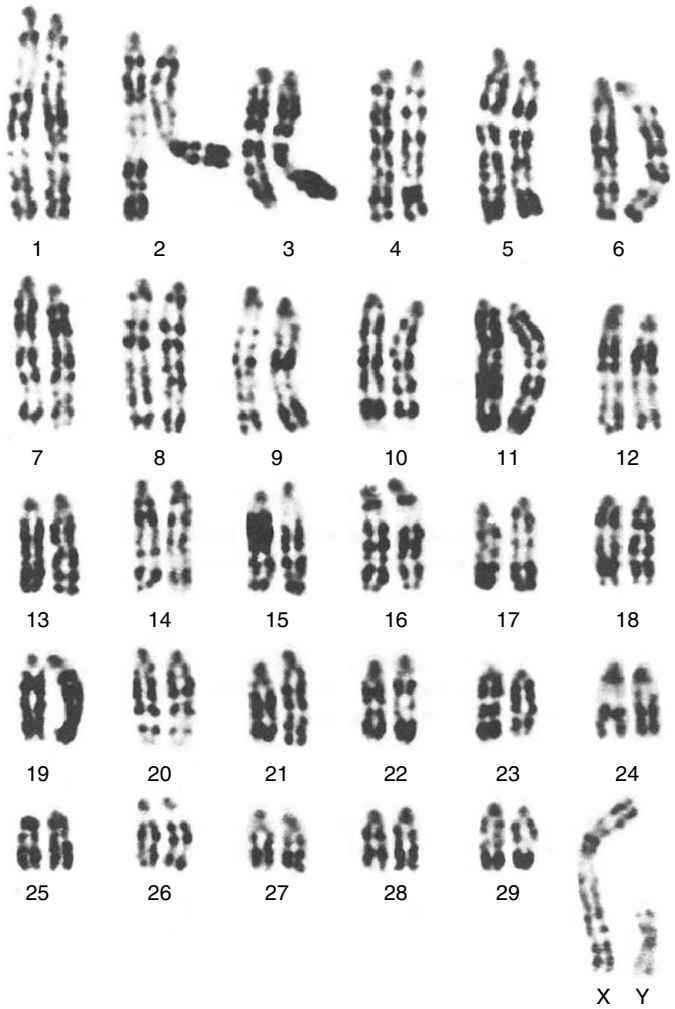

Fig. 3 R banded Bovine Chromosomes (from Fries, R., Ruvinsky, A. (1999) *The Genetics of Cattle*, CABI Publishing, Oxford, UK).

markers on the chromosomes by *in situ* hybridization, or they can be clone-based maps where the genome is fragmented and cloned and the clones physically reassembled so that the location and orientation of the pieces in relation to each other is known. A third type of physical map uses somatic cell hybrids, where fragments of the target genome are transferred into cells of another species; statistical methods are then used to calculate the proximity of markers from their coretention in the hybrid cells. In contrast, linkage maps are assembled on the basis of relationship between markers deduced from patterns of recombination in families. The ordering of loci should correspond between physical and linkage maps, but the distances between loci will vary due to the differences in the way the relationship between them is worked out. The ultimate genomic map of a species will be its DNA sequence.

3.1 Somatic Cell Hybrids

The first maps of the bovine genome were created using somatic cell hybrids made by fusing bovine cells with immortalized rodent cells (usually mouse or hamster). The immortalized cells are deficient in a selectable marker, usually thymidine kinase; thus, to survive in selection medium they need to retain the bovine Tk gene. In practice, the rodent cells retain large fragments of bovine chromosomes. Using a panel of somatic cell hybrids it is possible, using statistical methods, to identify which markers occur on the same chromosome, and to a certain extent the order of markers. In 1993, the first bovine genome map was published with 30 synteny groups, which were identified using a somatic cell hybrid panel. With the exception of the X chromosome, the synteny groups were not assigned to chromosomes and designated U1 to U29.

3.2 *In situ* Hybridization

In order to assign markers to bovine chromosomes, the method of *in situ* hybridization was initially used. Originally, radioactively labeled gene probes were hybridized to metaphase chromosomes spread out on microscope slides. The slides were then coated with photographic emulsion and following development the distribution of silver grains was analyzed. The distribution of silver grains was then compared with the banding pattern of the stained chromosomes using statistical analysis to assign the physical location of gene to cytogenetic bands identified on the standard karyotype. All the unassigned synteny groups identified by somatic cell hybrids were assigned to chromosomes using radioactive *in situ* hybridization. However, this approach is not very precise, as the silver grains are widely dispersed and a large number of hybridizations were required to assign a probe to a particular band with confidence, and even then the localization was at low resolution. A refinement of this methodology was to use fluorescently labeled probes, in a method called *fluorescent in situ hybridization* (FISH). With FISH, the hybridized probe is visualized directly; this increases the precision of the method and as a result reduces the number of chromosome hybridizations necessary to be confident of the localization. Currently there are around 500 genes localized on chromosomes by *in situ* mapping. In addition to mapping genes, it is possible to localize the anonymous markers used in linkage mapping to chromosomes using

FISH by labeling the cosmid clones from which the anonymous marker was derived, and using it as the probe. This approach allowed the physical bovine map and the linkage maps to be aligned.

The FISH approach allows the chromosomal band harboring the target sequence of the probe to be identified, and has a resolution at the DNA level of 2 Mbp or more. A higher resolution can be obtained if less condensed chromosomes, or indeed cloned DNA strands are used in the Fiber-FISH technique, which allows a localization of probes at a resolution of about a kilobase. The physical location of a probe to a chromosomal band obtained using the fiber-FISH approach also provides the information required for cloning of targeted regions by chromosomal microdissection.

Information obtained from somatic cell panels and *in situ* hybridization of genes demonstrated that in many cases the genes that came from the same chromosomal region in man or mouse also mapped to a single chromosome in cattle; indeed, genes from one region in one species was generally found close together on a chromosome of another, as shown in Fig. 4. This suggested the organization of the genomes of divergent species has been conserved during evolution. The extent to which this organization is conserved has been elegantly demonstrated using chromosomal probes derived from one species to ''paint'' the chromosomes of another using a ZOO-FISH approach. ZOO-FISH suggested that there are about 50 conserved segments of genome between the human and bovine genomes.

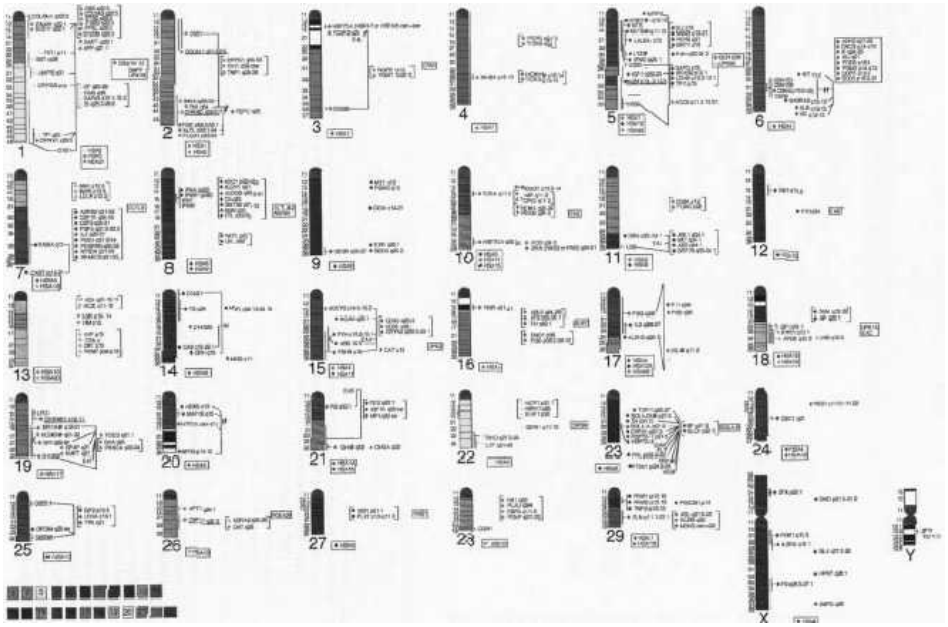

Fig. 4 Painting bovine chromosomes with human chromosome paints shows that large regions of chromosomes are conserved across species, at least at the gross level. (From Solinas-Toldo, S., Lengauer, C., Fries, R. (1995) Comparative Genome map of human and cattle, *Genomics* **27**, 489–596.)

3.3 Linkage Mapping

Linkage mapping relies on recombination occurring less frequently between markers that are close together than those that are more distant on chromosomes. Therefore, by analyzing the inheritance of markers in families it is possible to build a genetic map based on the frequency of recombination, or linkage, between the markers. To build a genetic map, there are two requirements: families of animals in which the inheritance of chromosomes can be tracked, and markers that are highly variable (polymorphic) so that in the majority of cases the parental origin of the marker can be determined. By combining the information on the inheritance of a large number of markers within families, it is possible to construct a genetic map by analyzing the recombination frequency between pairs of markers.

Creating genetic maps for cattle has two immediate problems: firstly, cows generally have singleton calves, and secondly, the generation for period for cattle is relatively long; therefore, cattle families are usually small. Producing a reasonable number of full siblings by natural breeding is both a long-term and expensive exercise. If conventional cattle families were used, in general, two parents and their calf would have to be typed for each marker. The situation in commercial herds is generally better as artificial insemination is used for breeding cattle and hence large half-sib sire families are readily available. Half-sib commercial populations have been extensively used for mapping the loci involved in the control of commercial traits, but in practice the contribution of the dam to the mapping information is limited, as she will only contribute one or two calves. For the construction of the genetic maps, large full-sib families are much more efficient. Fortunately, multiple ovulation embryo transfer (MOET) technology has been developed for cattle, which means a large number of progeny can be produced from two parents. MOET has allowed relatively large full-sib populations to be assembled as ''reference populations'' for genetic mapping. The advantage of full-sib families is that the effort required to type the markers is significantly reduced, while the resolution of the maps produced is increased. To obtain the highest density of markers on the genetic map, it is of benefit for all workers in the field to focus on a limited number of mapping populations. The international efforts to create bovine linkage maps focused on two reference populations: one, an international collaboration led by Australia with full-sib families provided by Australia, Kenya, Europe, and the United States to create the International Bovine Reference Pedigree (IBRP), and the second, focused on a reference population produced by the USDA Meat Animal Research Center in Nebraska. The distinction has been drawn between *reference* families, which have been specifically created and used to make genetic maps, and *resource* families, which have been assembled to localize the genes involved in particular traits.

The second requirement for constructing a genetic map is the markers. Whereas *in situ* hybridization and somatic cell hybrid mapping simply requires probes for the markers that can be hybridized to the DNA, the resolution of the linkage map is governed by the number of informative meiosis, that is, the more frequently the parental origin of markers can be determined the higher the resolution. Thus, it is important that the markers used for linkage mapping are highly polymorphic in the reference families. In general, genes

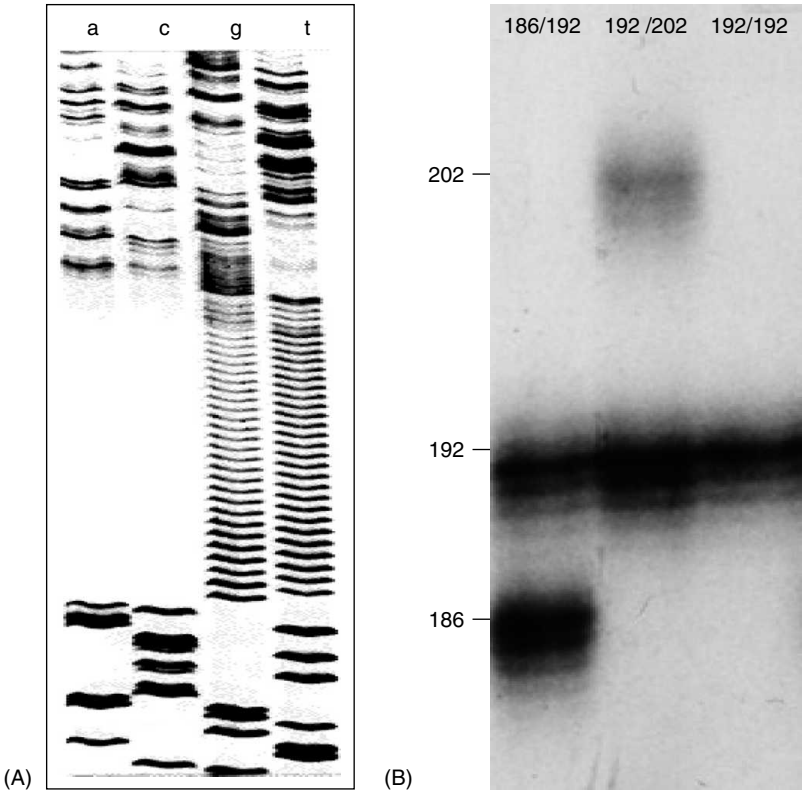

Fig. 5 Panel A. A sequencing gel showing a microsatellite locus with 31 repeats of the GT dinucleotide motif. Panel B. A microsatellite marker labeled with a radioactive isotope and visualized by exposure to photographic film. The marker has three alleles with sizes shown in base pairs along the side. The genotypes of each individual is shown at the top.

have less variation than the intervening DNA sequences; therefore, markers selected from anonymous stretches of DNA between genes have been mostly used to construct the linkage maps. The preferred type of ''anonymous'' marker is based on microsatellite loci. These loci are tandem repeats of simple sequences 1 to 4 bases in length, the most common being dinucleotide repeats of alternating C and T. Microsatellite loci seem to have a high mutation rate, which is thought to arise from DNA strand–slippage during replication, giving rise to variable numbers of the repeat (see Fig. 5). Therefore, each locus has a relatively large number of alleles, typically between 3 and 10. The number of alleles at a microsatellite locus is approximately proportional to the number of copies of the repeat unit. These microsatellite loci occur at about 40-kbp intervals and cover the whole genome, and therefore provide excellent markers for linkage mapping. By constructing primers flanking the microsatellite locus, the polymerase chain reaction (PRC) allows rapid genotyping of the marker.

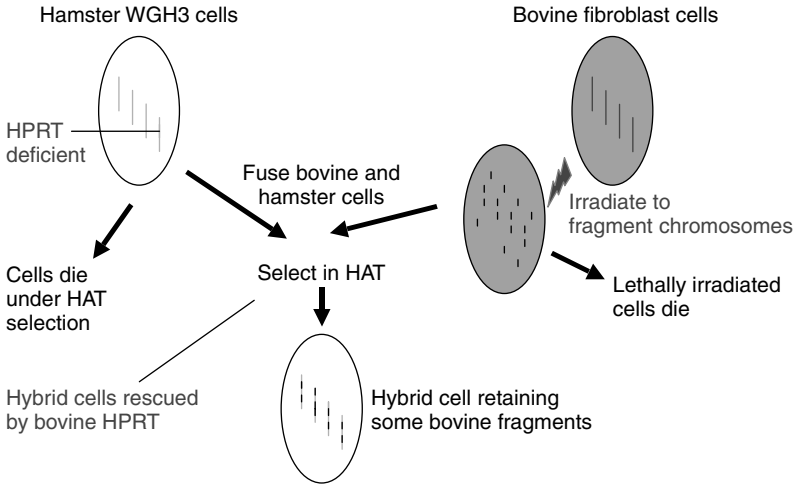
The international mapping effort produced sequence information for a large number of these microsatellite loci during the early 1990s, which were then genotyped in the IBRP and MARC reference families to produce genetic maps. Each of these maps had around 1000 markers, mostly the microsatellite loci. Some of the markers were specific to one or the other map, while a large number of markers were common to both. In addition to the genetic maps produced using the reference families, resource families have been typed for a large number of microsatellite loci in order to localize the genes involved in various traits; some mapping studies have published genetic maps based on the information generated from the resource herd they used. As a significant number of the markers used to localize the trait loci are common between the studies, and are also in common with the genetic maps, the information can be combined to improve the resolution and confidence of ordering of the loci included in the maps. A series of international chromosome workshops, held under the auspices of the International Society for Animal Genetics, have assembled the various data into consensus maps. There are now well over 2400 microsatellite markers mapped on the bovine genome (see http://locus.jouy.inra.fr/cgi-bin/lgbc/mapping/common/intro2.pl?BASE=cattle or http://sol.marc.usda.gov/genone/cattle/cattl.html).

3.4 High-resolution Maps

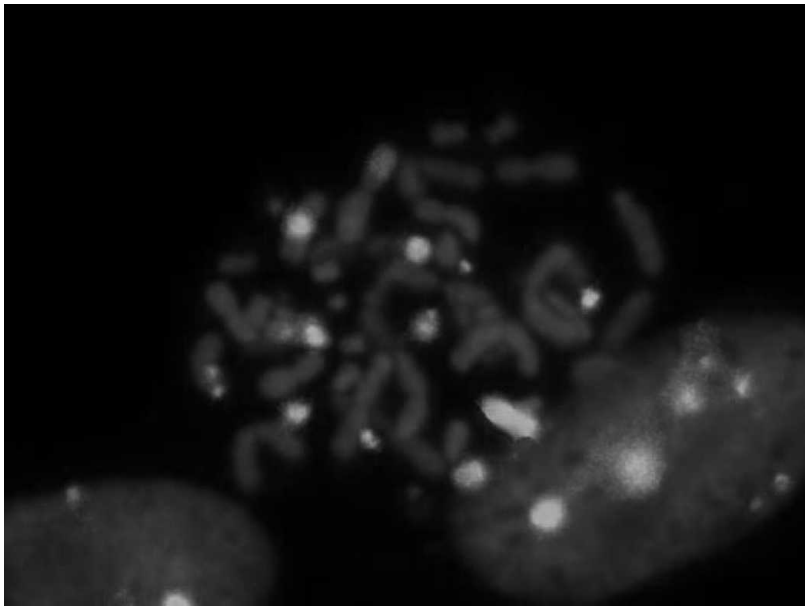
Both *in situ* hybridization and linkage-mapping approaches have limitations with respect to creating detailed genome maps: the resolution of both is limited: the *in situ* approach, by the physical limits of observation, and linkage mapping, by the size of resource families used, and hence the number of informative meiosis available to order markers. A further drawback of the linkage-mapping approach is that the markers must be polymorphic, so that alleles on different parental chromosomes can be readily identified to track the inheritance of the chromosomal regions. The gross conservation of synteny between genomes discussed above may be disrupted at the level of gene order, with blocks of genes being rearranged within a broadly conserved framework. It is, therefore, important that mapping studies are able to include genes within the maps, which can then be used to compare genomic organization across species. Genes show much more limited levels of polymorphism than the microsatellite loci, and hence are more difficult to place on linkage maps accurately.

3.5 RH Mapping

Like linkage mapping, the radiation hybrid (RH) mapping approach relies on markers that are close together in the genome being separated less frequently when chromosomes are broken than more distant markers. In the case of RH mapping, the separation of markers is achieved by random fragmentation of the genome by radiation, rather than by recombination. An RH mapping-panel is constructed by irradiating cells from the target species, which are then fused with immortalized recipient hamster cells as shown in Fig. 6. The hamster cells used are deficient for a selectable marker (TK or HPRT); thus, growth in selection medium requires the retention of the region of the donor genome that carries the selectable marker; however, in addition many other fragments, typically between



(A)



(B)

Fig. 6 Panel A: Construction of Radiation Hybrid cells. Fragments of the donor (bovine) chromosomes are retained in the immortalized rodent (hamster) cells that are rescued in selection medium by retaining the selectable marker from the donor genome. Panel B illustrates the presence of bovine genome fragments in the RH cells of the Bovine 3000 rad RH panel Williams, J.L., Eggen, A., Ferretti, L., Farr, C., Gautier, G., Amati, G., Ball, G., Caramori, T., Critcher, R., Costa, S., Hextall, P., Hills, D., Jeulin, A., Kiguwa, S.L., Ross, O., Smith, A.L., Saunier, K.L., Urquhart, B.G.D., Waddington, D. (2002) A Bovine Whole Genome Radiation Hybrid Panel and Outline Map, *Mamm. Genome* **13**, 469–474. (Photograph kindly provided by Dr C Farr Department of Genetics University of Cambridge).

15 and 40% of the donor genome is retained in each hybrid. A panel of RH cell lines is assembled in which each line contains different combinations of fragments from the donor genome. The presence or absence of markers in the cells of the hybrid panel is then used to calculate the relationship between the markers and build them into the RH map.

The RH approach has two major advantages over physical mapping by *in situ* hybridization and genetic-linkage mapping. Firstly, changing the radiation dose used in the construction of the panel allows panels with different resolutions to be created and secondly, the markers do not need to be polymorphic to be included in the map. Three RH panel have been described for cattle, two of which were constructed using a relatively low radiation dose (3–5000 rads) and one higher resolution panel (12 000 rads). There are now over 2000 markers mapped on the low-resolution panels and framework maps published. The inclusion of a proportion of microsatellite in the RH maps allows them to be aligned with the genetic maps (see Fig. 7). However, the main advantage of the RH panels is to allow the inclusion of genes or ESTs in the bovine map and so detailed comparative maps between the bovine and other genomes can be made.

3.6
Sequence Ready BAC Contigs

Identifying the genes involved in particular traits in cattle is currently carried out by linkage mapping followed by a positional candidate gene approach. This approach identifies genes that may be expected to be involved in the trait because of the function of their products and which map within the appropriate region. The candidate genes are then tests for involvement with the trait. This approach relies heavily on comparative mapping information to make use of data available for the human genome to provide the positional candidate genes. In the absence of positional candidate genes, or if the candidate genes identified do not prove to be the genes involved in the trait, the next approach is to construct a set of overlapping contiguous clones (called ''Contigs'') spanning the region of the chromosome that harbors the target gene. Contigs are usually constructed using clones containing large fragments of inserted genomic DNA, either cosmids (~40 kbp inserts), YACs (up to 1 Mbp inserts) or BACs (100+ kbp inserts). Construction of contigs is usually achieved by screening the large fragment libraries with markers that are available for the region of interest, then joining the clones together by ''walking,'' which is achieved by using a probe from the end of one clone to find the next, and so on until clones covering the region of interest are found.

As the chromosomal locations for the genes controlling more traits are discovered, it becomes sensible to assemble a whole genome contig in which the clones from a large fragment library are placed in order along the each of the chromosomes. The whole genome contig then provides easy access to clones for particular regions for local sequencing and gene hunting projects. Selection of a ''minimum tiling path'' which contains the minimum number of overlapping clones to span all the chromosomes also provides the ideal underpinning resource from which to sequence the genome.

At the time of writing, the assembly of a whole genome BAC contig for the bovine genome is under way. The approach adopted is to use a BAC fingerprinting technique for the initial ordering

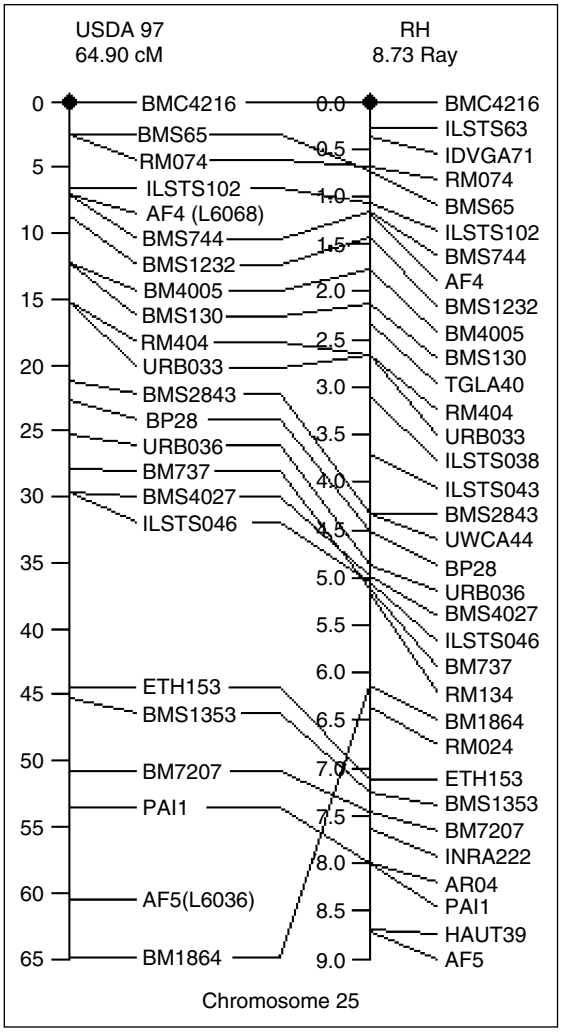


Fig. 7 Examples of genetic and RH maps for chromosome 25. The order of markers is broadly the same between methods; however, the relative distance between markers varies (from Williams et al. 2003).

of the clones. With this approach, BAC clones are digested with two restriction enzymes and sophisticated software is used to match fragment sizes and identify clones that contain regions of DNA that are common by identifying shared restriction fragments. The contig assembled from the fingerprinting is then confirmed by end sequencing the BACs and checking for overlapping sequence. With the availability of the human sequence, the BAC sequences can be used to align the bovine contigs with the human genome. However, interruptions in the conservation of synteny between human and bovine genomes may introduce errors into the ordering of the contigs; thus, it is unlikely that this approach will generate a continuous contig of all chromosomes. The order and orientation of contigs in the bovine genome will therefore be confirmed by aligning the BAC contig with the bovine

RH maps by typing markers in common between the BACs and the RH maps.

Two BAC libraries are currently being fingerprinted and the results merged. At the British Columbia Cancer Agency, 280 000 cattle BAC clones have been fingerprinted from libraries created at the BACPAC resources (Children's Hospital, Oakland Research Institute, Oakland, California), while at INRA in France, 90 000 clones have been fingerprinted. These data are currently being merged to produce the around 15-fold BAC clone coverage of the bovine genome. End sequencing of the BAC clones has just started and is being undertaken by the international bovine research community. The database of results will be maintained at The Genome Sciences Center, Vancouver, British Columbia, Canada. In parallel, the Texas and Roslin RH panels are being used to assist with the ordering of the clones.

3.7 Sequencing the Bovine Genome

The Human Genome Project announced the completion of the first draft of the entire human sequence in 2001 with the essential completion of the human genome sequence in 2003. This provides a vast resource for understanding the organization of the human genome and provides the template against which other genomes can be compared. The availability of the human sequence will also allow scientists to identify new genes and explore the evolutionary history of genomes. However, on its own the information contained within the human sequence is limited compared with the potential information that can be obtained by comparing and contrasting genomes between closely and distantly related species. Comparing the differences as well as the similarities between genomes is the key to understanding the functionally relevant features. Therefore, in addition to decoding the genetic makeup of humans, the sequence of a number of model organisms are also being analyzed, including baker's yeast, the roundworm, the laboratory mouse, and a rough draft of the sequence of the rat genome was produced in November 2002. The construction of the complete physical map of the bovine genome, by linking contiguous BAC clones to span all chromosomes, provides important resources that are the foundation for a bovine genome-sequencing project. The shotgun sequencing approach has inherent problems associated with assembling sequence data, whereas the identification of ordered BAC contigs and the clones constituting the minimum tiling path, provide the framework and the means to assemble the genome sequence efficiently. At the time of writing, a bovine genome-sequencing project is underway at Baylor College of Medicine Sequencing Center (see http://hgsc.bcm.tmc.edu/projects/bovine/)

4 Identification of Genes Controlling Traits

Genetic improvement of cattle has focused on traits that impact on profitability of agricultural enterprises; traditionally this meant increased output. Simple production traits are easiest to measure and so have been used in conventional selection programs with great success. However, using modern methods selection on a broader spectrum of traits can be considered and other traits that impact on profitability and welfare, such as

feed-conversion efficiency, health, fertility, and product quality can be included in the selection objectives. If selection is phenotype-based, improvement in one trait is compromised by simultaneously including other traits in the breeding goals. However, using information on the genes controlling the traits potentially allows for selection on genotype and hence on several traits simultaneously. In theory, once sufficient knowledge is available, individuals carrying beneficial genes for several traits could be identified using DNA markers and mated to produce progeny with the desired characteristics. While we are a long way from this level of knowledge, work is under way to identify the genes involved in a wide range of traits. The ultimate goal of molecular genetics is to understand how allelic variations in the genes controlling various traits interact and result in the observed variations in the phenotype. Progress toward an understanding of the genetic control of traits can be achieved if the location in the genome of the genes involved is known, and markers linked to the genes are found. Once information has been accumulated to predict the alleles present in an individual, these linked markers can be used to aid breeding by marker-assisted selection (MAS).

Identifying the genes involved in the control of traits can be approached in a number of ways. Information on the physiology of the trait can be used to identify the biochemical pathways involved and hence postulate the controlling genes. This information can be coupled with patterns of expression among tissues to facilitate cloning of the gene(s) likely to affect the trait. These ''candidate'' genes are then studied in the context of the trait to identify if they play a role in controlling the observed variation. This approach clearly requires a good *a priori* knowledge of the trait and its physiology, but even so it could result in important genes being missed if they are not obviously involved in the known physiology. The second approach is to start with no prior assumptions regarding the physiology or genes controlling the trait, and to use a genome-mapping approach. The mapping approach is often necessary, particularly with complex traits where the various gene interactions cannot be predicted. In the same way as building a genetic map, mapping the genes that control particular traits requires families in which to track the inheritance of chromosomal regions. These families have to be segregating for the trait of interest and information quantifying the trait has to be collected. The mapping process involves tracking inheritance of chromosomal regions using DNA markers and then correlating inheritance of the markers with inheritance of characters associated with the trait. In practice, identification of the ''trait genes'' is achieved using a combination of the genetic mapping and candidate gene approaches.

4.1 Mapping Quantitative Trait Loci (QTL)

Production associated traits in cattle usually display continuous variation, such as growth or milk yield, and are called ''Quantitative Traits.'' Variation in these traits is controlled by several loci, called *quantitative trait loci* (QTL). Two approaches have been adopted for mapping QTL, one is to make use of commercial cattle herds and the second is to use specifically bred cattle populations to examine particular traits. The advantage of using commercial populations is that they already exist and that simple measurements are recorded at a national level. In contrast, the resource population has to be specially bred;

however, this provides the opportunity of starting from diverse founders that allows the genetic and phenotypic variation in the trait(s) of interest to be maximized. Access to experimental resource herds also extends the possibility of recording the "difficult to measure" traits such as feed-conversion efficiency or immune response to pathogens, which would be impossible in a commercial context. The choice of using commercial or resource populations is to a large extent dependent on the trait that is being considered.

4.2 Dairy Traits

Both of the approaches described above, using candidate gene or genome-mapping approaches have been used to look for genes controlling traits that are important for milk production. The candidate gene approach has focused on the genes coding for the constituent proteins in milk. Milk is mainly water, typically around 88%, containing about 5% lactose, 3.5% fat, and 3.5% protein together with a number of minor components. Of the protein fraction, 80% are the caseins, which precipitate from milk at low pH and form the curd. The remaining whey proteins include β-lactoglobulin, α-lactalbumin and lactoferrin. There are 4 casein genes in cow, α_{s1}, α_{s2}, β and κ, which are clustered within a 25-kb locus on chromosome 6 (6q31), shown in Fig. 8.

Given the high proportion of casein forming the milk protein fraction, and that they are the chief constituents of the curd, which is used in cheese making, the casein genes have been extensively studied. The role of κ is in stabilization of casein micelles in liquid milk and cleavage of κ-casein (CSN3) leads to precipitation

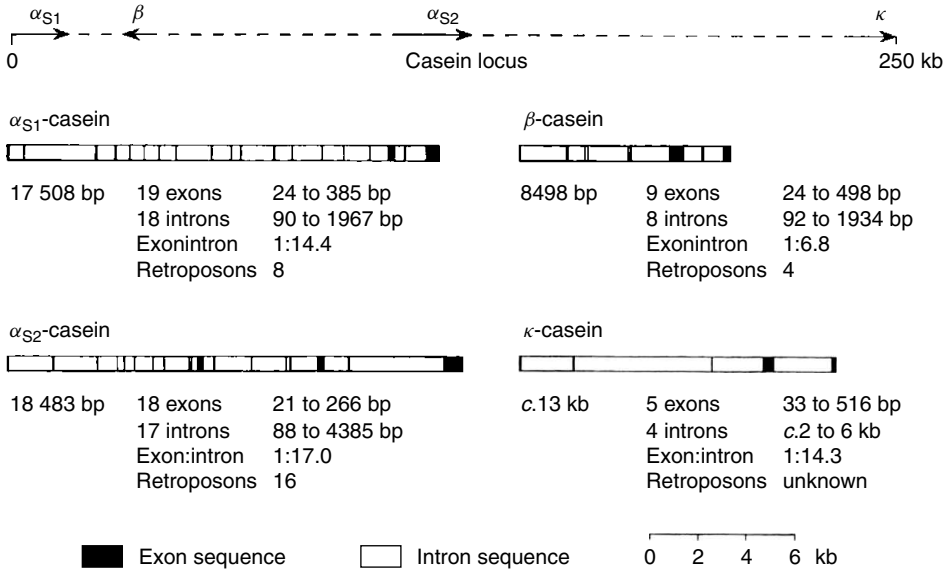

Fig. 8 Schematic representation of the bovine casein gene depicting the exon structure as well as their organization within the casein locus (from Fries, R., Ruvinsky, A. (1999) *The Genetics of Cattle*, CABI Publishing, Oxford, UK).

of the caseins in cheese production. Two alleles of the CSN3 gene have been described, of which the B allele has been associated with improved manufacturing properties of milk. The B allele has also been associated with increased milk production, but only in Holstein cattle and not in other breeds. Determining the various alleles at each of the 4 casein loci allows casein haplotypes to be constructed, some of which have been associated with increased milk production in other breeds. This may suggest that genes linked to the casein locus, rather than the casein genes themselves are responsible for the variation. Additional interest has been focused on polymorphisms in the β-casein gene (CSN2), where there has been the suggestion that the A2 allele may be associated with protection from diabetes.

Selection for improved milk production has been achieved through progeny testing, which has resulted in milk yields in the Holstein breed nearly doubling in the past 40 years to 10 000 liters per 305-day lactation today. In developed countries, the Holstein represents the most numerous cattle breed and accounts for the majority of milk produced. The consequence of intensive selection has been the narrowing of the genetic base of the population and the wide-scale use of a relatively small number of ''elite'' sires, many of which are closely related. As a result, the dairy industry has very large half-sib families in commercial herds sired by a limited number of sires. While selection for milk yield has produced, in the Holstein breed, cattle with dramatically increased milk yield, there have been an associated decrease in protein content of the milk, decreased fertility, and increased incidence of lameness.

While resource herds have been used to address dairy associated traits, so far few of these results have been published. Most of the data available on QTL involved in dairy associated traits has come from studies on the commercial dairy population, the structure of which, as discussed above, is well suited to genetic mapping studies. However, the range of traits that is routinely recorded in commercial herds is limited, and the focus is on simple traits such as milk yield plus protein and fat composition, and somatic cell scores, the latter being related to the incidence of mastitis. In some cases, ''linier type'' (conformation) traits are also recorded. The major issue to be considered when addressing improvement in dairy traits is that they are often sex specific, and that the production animals are female, whereas selection is applied to the males. Thus, the industry requires females that produce large quantities of milk, have healthy udders and high fertility, while selection is on the bulls that display none of these traits. Genetic mapping studies could be carried out by tracking the inheritance of chromosomal regions from sires into their daughters, on which the traits are recorded, in a so-called daughter design study. However, this approach is inefficient for several reasons: firstly, a considerable number of daughters would need to be genotyped with DNA markers to track inheritance of the chromosomal regions from a single sire, and secondly, the sire has to be segregating for polymorphisms both in relevant genes and also for phenotypic variations in the trait, for many sires this will not be the case. An alternative approach, proposed by Weller et al., is the ''Granddaughter design study'' where a small number of males (bulls) are used to produce a large number of sons. DNA markers are used to track the chromosomal inheritance between the bull and his sons. The sons in their turn are used to sire a large number of daughters, on which the production traits are

measured. The phenotypic measurements on the daughters are then used to calculate the genetic merit of their sire (the son of the elite sire). This is the basis of the progeny test used to select breeding sires. By correlating DNA marker information with the predicted breeding values, trait genes can be mapped.

The use of data collected on commercial herds to map QTL was pioneered by Georges et al., who used the US Holstein population to map QTL involved in milk yield and quality. The study used 1518 progeny tested bulls with production data from over 150 000 cows to derive their performance information. The sires were genotyped with 159 microsatellite loci, and analysis of the phenotypic and DNA marker information allowed 5 QTL to be identified, on chromosomes 1, 6, 9, 10, and 20. Each of the QTL was involved in different combinations of the traits examined, namely: milk yield, fat, and protein percentage, and fat and protein yield. As each of the QTL was identified in a subset of the sire families, it is unclear if these results indicate that the different QTL affect different traits, or whether the differences are because each of the sires and grand sires was segregating for different combinations of the QTL. Subsequent studies in other populations have independently confirmed one or more of the QTLs from the Georges study. An additional QTL for milk yield and composition has been reported on chromosome 14, which has been fine mapped and the likely trait gene identified (see DGAT1 below).

4.3 Beef Traits

The structure of the beef industry is different from the dairy industry in a number of ways. Beef is produced from a large number of breeds, which have not been under as intensive selection as seen with the dairy breeds. The conditions under which beef cattle are raised also vary considerably, maintaining the need for diversity of production animals. Breeding in beef units is often by natural service, and where AI, is used the number of progeny produced per bull is considerably fewer than seen with dairy breeds. There is some systematic recording of growth, fat, and conformation traits in a number of countries providing the opportunity for QTL mapping for beef production traits. However, the majority of published information on QTL for beef-associated traits comes from specifically bred resource herds. Several resource herds have been created worldwide, including herds at Texas A&M University (USA) and CSIRO (Australia) that have been produced by crossbreeding between *B. indicus* versus *B. taurus* to produce an F2 population to address meat quality traits. *Bos indicus* cattle, while more tolerant of drought, produce meat that is typically tougher than that of *B. taurus* breeds. Work by the Meat Animal Research Center in Nebraska using crosses between several breeds, has mapped QTL for several beef-associated traits, including growth rate, muscle mass, fat, and so on. A dairy x beef (Jersey vs Limousin) F2 resource herd has been bred in Adelaide (Australia) to specifically address traits associated with beef production. Progeny from this herd have also been raised in New Zealand, which will enable QTL affecting production in *intensive* systems (Australia) to be compared with those that are relevant in *extensive*, grass-based systems (New Zealand). Results of this study are due to be published. A conceptually similar herd, produced as F2 and reciprocal cross between dairy and beef breeds

(Holstein and Charolais) at the Roslin Institute, is also addressing the identification of QTL involved in beef production; however, in addition, an extensive portfolio of traits including health and fertility traits is being recorded on this population. This approach will allow pleiotropic interaction between traits and QTL to be addressed.

4.4 Health Traits

Whereas one of the primary drivers in natural selection will be health and resistance to disease challenge, the intervention of man in the selection of livestock species has, up to now, ignored health traits as selection criteria in favor of productivity traits. In some cases, productivity is dependent on health; however, with the increasing dependency on veterinary interventions, the natural defense mechanisms of the individual have been largely ignored. With the increasing demand from consumers for naturally produced products, together with the break down in effective antibiotic treatment caused by drug resistance in pathogens, there is an increased need for selection of animals with improved natural resistance to disease.

Much attention has been focused on the bovine major histocompatibility complex (MHC) as a potential locus that regulates immune response. The MHC region in cattle, in common with other mammals, contains genes coding for the class I and class II MHC molecules. T cells, that are responsible for eliciting an immune response do not recognize foreign antigens in their native form, but require specialist cells (B-cells, macrophages etc.) to process the antigen and present it bound to MHC molecules on their surface before a specific immune response is triggered. Variations in binding affinity of the antigens to the MHC molecules results in variations in the active immune response directed toward that antigen: failure of the antigen to bind to the MHC molecule means that it is not presented to T cells in the correct context and thus no immune response ensues. The bovine MHC (BoLA – bovine lymphocyte antigen locus) is located on chromosome 23 and in addition to the MHC antigens the region codes for 30 to 40 other genes including several immunologically active proteins, such as tumor necrosis factor and proteins of the complement system. There are two distinct classes of MHC antigen. The class I antigens are composed of two chains, a class I heavy chain that is encoded within the MHC region and β_2-microglobulin whose coding gene is located elsewhere in the genome. The class I molecules present antigen to cytotoxic T cells whose function is to kill infected cells, for example, with virus. There are around 20 MHC class I genes spanning about 1.5 Kb within the BoLA region. The class II molecules are composed of α- and β-chains, both encoded by genes within the MHC region. Several class II genes exist in cattle that resemble their counterparts in other mammalian species, namely, *DQ* α and β, and *DR* α and β genes, also DYA, and the class II-like chaperone molecule DMA. In the cattle, the *DR*β gene has been duplicated in some haplotypes, while the equivalent of the human, the DP locus appears to be absent in the BoLA region. The class II genes are involved in presentation of antigen to T-helper cells that promote both cellular and humoral immune responses. Given the central role of the MHC molecules in promoting immune response, it is not surprising that associations between MHC alleles and immune response to various infectious diseases and parasites have been sought.

The most common disease in dairy cattle is mastitis, which is an infection of the udder, and can be caused by several pathogens. Mastitis is both a welfare and an economic problem, resulting in decreased milk yield, increased veterinary treatments and is the most common cause of death in dairy cattle. The incidence of mastitis is not generally recorded, except in Scandinavian countries where a national health-recording scheme keeps individual records of disease for every cow. Studies using the Scandinavian data have identified putative QTL on chromosomes 3, 4, 14 and 27 associated with mastitis incidence. More commonly, somatic cell scores (SCS) are used as an indicator of mastitis incidence, although SCS are a measure of inflammatory response, and do not necessarily indicate clinical or subclinical infection. Consequently, the correlation between clinical mastitis and SCS range from 0.37 to 0.97. However, this is a measure that is routinely recorded in commercial dairy herds. Studies to examine associations between genetic loci and SCS suggest that some MRC DRβ alleles may be associated with increased SCS and hence increased risk of mastitis.

Breeds of cattle are known that show resistance to particular parasites, for example, the N'Dama cattle of West Africa are resistant to *Trypanosoma congolense*, which causes sleeping sickness, whereas other breeds of cattle are highly susceptible to this disease. The introduction of more productive breeds into endemic areas is currently not a feasible option, as the animals would either die or be too expensive to maintain through requirement for extensive veterinary treatment. However, the disease resistant breed is small and not very productive. One approach to allow the introduction of more productive breeds in to infected areas is to identify the genes controlling the disease resistance and introduce these resistance genes into more productive animals. In order to identify the genetic control of *T. congolense* infection, an F2 cattle resource population was bred at ILRAD (now ILRI) in Kenya by crossing N'Dama with Boran cattle, the latter being susceptible to trypanosomiasis. This study has identified QTL to be involved in resistance; and fine mapping of these loci is being pursued in a mouse model.

A new cattle disease was identified in the United Kingdom in 1986, called *bovine spongiform encephalopathy* (BSE). The BSE epidemic developed rapidly to peak in 1992. Today, more than 180,000 cases have been confirmed in the United Kingdom. In sheep incidence of the related transmissible spongiform encephalopathy, scrapie, is associated with polymorphisms in the *PrP* gene, at codons 136, 154, and 171. Sheep that are homozygous for glutamine and position 171 are most susceptible to scrapie, while individuals with arginine are most resistant. In cattle, two polymorphisms have been reported in the coding region of the *PrP* gene, a silent change that affects a *Hind*II restriction site, and a difference in the number of G-C rich octa-repeat elements, with alleles that have either 5, 6, or 7 copies of the repeat. Two case-control studies found no association between variations in the octa-peptide-repeat and incidence of BSE. Complete sequence information for a 25-kb region containing the bovine *PrP* gene revealed 9 polymorphisms in the PrP coding region, including the two mentioned above, and more than 40 SNPs and insertions in noncoding regions of the gene. However, there is no evidence to date for polymorphisms within the bovine *Prnp* coding region that affect susceptibility to BSE. A whole genome scan with microsatellite

markers that examined transmission disequilibrium of alleles between BSE affected and control progeny bred from a small number of bulls revealed three loci, on chromosomes 5, 10, and 20 that were associated with incidence of BSE. The interval on bovine chromosome 10 coincides with the corresponding interval on mouse chromosome 9 that has been associated with resistance of mice to experimental scrapie and is now being investigated further.

4.5 Identifying the Trait Genes

The ultimate objective of the genome-mapping work is to identify the genes and variations within the genes that control the traits of interest. Up to now a reasonable number of genes controlling a diverse range of traits have been localized to fairly broad regions on many bovine chromosomes. Typically, linkage-mapping studies in cattle have identified, at best, a 20-cM interval (the whole bovine genome is 3000 cM) within which the gene affecting the trait of interest is located. This size of the interval represents 20 Mbp of DNA and, assuming a conservative estimate of around 30 000 genes in the bovine genome, is likely to contain at least 200 and possibly as many as 1000 genes. There are several ways of identifying the gene involved in controlling a trait from its map location; these include fine mapping using meta-analysis of data from different populations to refine the map location, examination of haplotypes to identify the limits of linkage disequilibrium between markers and the trait, positional cloning using large fragment clones to build contigs across the QTL region, and a positional candidate gene approach, where genes likely to be involved in the trait are identified within the QTL region. In conjunction with these approaches, comparative information can be used, taking information about the position and role of candidate genes from other species and using knowledge of conservation of synteny to identify candidate genes likely to be located within the QTL region in cattle.

Two studies have been published that are paradigms for identification of genes involved in meat and dairy traits in cattle. Both these studies used a mixture of linkage mapping, positional cloning, and comparative genomics to identify the gene controlling double muscling, and a gene for milk production in cattle.

Double muscling is an extreme form of muscle development that has been described in several breeds of cattle; the most extreme form of double muscling being seen in the Belgian Blue breed. Segregation patterns for the trait suggested that the phenotype was controlled by a single gene, which was subsequently mapped to chromosome 2 using a resource herd bred from double-muscled Belgian Blue cattle crossed to nondouble muscled cattle. The first approach for identifying the gene controlling the phenotype, starting from the map position, was to test candidate genes located close to the region identified from the mapping study. However, this approach failed to identify the trait gene. At the same time, unconnected work on mice identified a new member of the growth and differentiation factor β superfamily of genes (GDF-8) that was expressed in muscle and that was required for normal muscle development. Knocking-out the expression of GDF-8 resulted in hyper-muscularity in the mice and therefore was named myostatin. Using RH mapping, myostatin was shown to map to bovine chromosome 2 within the interval where the double-muscling gene had been mapped. Sequencing the

myostatin gene from double-muscled individuals revealed an 11 bp deletion in Belgian Blue cattle that truncates the protein in the bioactive c-terminal domain, and a single nonconservative base change in the double-muscled Piedmontase breed. These mutations are strongly associated with the double-muscled phenotype and make myostatin the likely causative gene.

It has been suggested that double muscling originated in the British Beef Shorthorn breed. However, the myostatin gene in cattle is highly polymorphic, with 19 polymorphisms currently described within the bovine gene. Analysis of the distribution of these polymorphisms has allowed the possible origins of the alleles found in different breeds to be investigated. There is currently no molecular evidence to support the Shorthorn as the origin of the myostatin alleles responsible for double muscling in European cattle. The 19 polymorphisms can be assembled into 10 haplotypes, which are related in a broad phylogenetic tree with a shallow timescale, suggesting that most of the mutations have accumulated independently, and fairly recently. The 11-bp deletion seen in Belgian Blue cattle is the most common mutation responsible for double muscling and it is likely that this allele was introduced into several other breeds from a single source at about the same time. Independent, rather than a stepwise accumulation of mutations then followed.

The effects of the disruptive mutations in the myostatin gene on the phenotype vary between the different breeds. The same 11-bp deletion that is found in the Belgian Blue and which is associated with an extreme form of double muscling, is associated with a milder phenotype in other breed, such as the Spanish Asturiana and British South Devon cattle. This has lead to speculation that modifiers must interact with myostatin in the regulation of muscle development and are partly responsible for the double-muscled phenotype.

A QTL with effect on milk production, particularly fat content was localized to chromosome 14 in cattle using a linkage-mapping approach in several commercial populations. The fact that the same QTL location was identified independently gives confidence both in the existence of a locus with significant effects on milk synthesis, and also on the position of the QTL. By examining the extent of linkage disequilibrium on individual chromosomes, the QTL region was narrowed. Individual recombination events between marker and the phenotype allow most of the mapped QTL region to be discounted as the location of the gene, so that the trait gene could be localized to within 3 cM, representing 3 Mb of DNA. A BAC contig spanning this region was assembled in preparation for local sequencing to identify genes within the region.

Work carried out in parallel in mice identified diacyl-glycerol *O*-acyltransferase (DGAT1) as an enzyme involved in the formation of triglyceride, which is a major component of the fat found in milk. Studies in mice also showed that females lacking both copies of DGAT1 had impaired lactation. DGAT1 was mapped within the QTL region on chromosome 14 in cattle by RH mapping and also mapped with the refined 3 cM interval on the BAC contig, making it a very strong positional candidate gene. Sequencing the DGAT1 gene revealed a polymorphism at position 232, which substitutes alanine for lysine (K232A). Individuals with lysine have a higher milk production than those with alanine.

5 Functional Genomics

Having a detailed genome map, even the ultimate map in the form of the sequence, of the genome, is only the starting point for identifying the genes controlling traits in cattle and understanding their function. The next step will be to characterize the expression of the genes, and the functions of their protein products, in order to understand their role in controlling development and survival of the individual and the variations seen among individuals.

Advances in technology mean that we can now examine the expression of large numbers of genes simultaneously, using a macro- or microarray approaches. These arrays are created using either cDNA probes, or oligonucleotide probes designed from knowledge of the gene sequence. The probes are anchored to a solid matrix, a nylon membrane in the case of the macroarray, or a glass slide for the microarray. Complex probes are then created by reverse transcribing and labeling the RNA from the cells or tissues whose gene expression is being studied. The labeled probe is then hybridized to the arrays and expression patterns deduced, either by comparison with a reference, or in the case of microarrays by simultaneous hybridization of the samples being compared, each of which is labeled with a different fluorescent dye. The prerequisite for these arrays are the gene probes that are used. Although specialist oligonucleotide probes have been made for particular genes, for example, those involved in immune responses, currently most array probes are cDNAs that have been identified by sequencing clones from cDNA libraries produced from the target tissue or tissues. The data generated from the sequencing cDNA clones produces expressed sequence tags (ESTs). At the time of writing, there are over 122 000 cattle ESTs sequences recorded on the EMBL sequence database, mainly generated by the USDA Meat Animal Research Center in Nebraska. These arrays will enable gene expression to be explored in a range of tissues in different physiological states and from animals with variable phenotypes. This information will provide an extension to the genome-mapping studies to help identify the genes involved in the control of traits, and to understand their function

6 In Conclusion

The construction of maps for the bovine genome has allowed the chromosomal regions harboring genes controlling specific traits to be identified, and in some cases the genes themselves have been found using a variety of techniques, starting from their map position. Comparative mapping information is allowing the alignment of bovine chromosomes with high-density maps in other species, and with the human genome sequence. This will provide considerable information on the range of genes present in the genome and their location in cattle. In the foreseeable future, the sequence of the bovine genome will be available. Analysis and annotation of the bovine sequence along with the sequence from other species will, in many cases, confirm the predictions made from the comparative mapping. Differences observed between genomes will also lead to new findings with the identification of new genes and a greater understanding of the regulation and expression of the genes and their role in controlling phenotypic variation.

Keywords

Animal Patent
The application of patent law to the protection of higher animals.

Intellectual Property Rights (IPR)
Legal systems for providing property protection for abstract ideas and knowledge, the systems generally including patents, trademark, and copyright, among others.

Patent
Instrument covering the grant of limited exclusive property rights to inventors; also utility patent.

Transgenic Animal
An animal to whose DNA (hereditary material) has been added DNA material from another source other than parental germplasm. Patented animals are typically transgenics.

Animal Patents refers to the granting of utility patents to higher animals. The application of patents to animals is a recent development in patent law with the first formal decision (in the United States) dating to only 1987. This extension of patent law raises for some legal, practical, and moral issues, yet others see patent protection as an essential incentive for the development of specialized animals for uses in medical research, medicine production, agricultural/aquaculture uses, and even pets. By 2004, some 600 animal patents had been granted worldwide, 80% in the United States, and most relating to ''animal models'' for medical research. Indeed, the first animal patent in 1987, for the ''Harvard'' mouse, was for cancer

research. The World Trade Organization agreement, while specifying minimal Intellectual Property Rights protection allowable in member states, does specifically allow countries to exclude patents for animals while offering no alternative protection systems. Hence, besides the United States and European Union (EPO members), only three countries presently allow patents for animals. Animal patents are likely to remain geographically limited for some time, but scientific advances and commercial realities will eventually lead to pressures on governments to grant protection. Public opinion surveys show the best acceptance for patented animals providing clear benefits to humans.

1 Introduction

Animal Patents refers to the application of patents to higher animals. Patents are a means of granting property rights and, by providing limited monopoly control, an incentive for investing in inventive research and development (R&D). Patents, a form of Intellectual Property Rights (IPR), have been found to provide an especially significant incentive for easily copied inventions, which includes self-reproducible animals. As a background, the general functioning of patent systems (known more formally as utility patents) is described in Sect. 2. Also included is the description of a specialized patentlike system for plants only, which, while not directly applicable to animals, does allow some insights into the special considerations and approaches for applying IPR to self-reproducing life forms.

While, at the most basic level, there is nothing conceptually different about applying patents to animals, their use does raise two fundamental issues:

- Are animals discoveries or products of nature and hence excludable from patents?
- Should ethical/moral considerations for patenting animals exclude patentability?

The focus here is on issues associated with patented higher animals, as contrasted with other economic and social matters applied to animals in general. As a practical matter, this means the animals that have been genetically transformed. Methods are important, but only to the extent they affect the production of transgenic animals. Cloning, for example, is a method that can be applied to transgenic animals but is not associated with the animals themselves. Also, while there is no specific bar to the patenting of traditionally bred animals and, indeed, plants produced through conventional breeding approaches are routinely granted patents, as yet grants for animals have been limited to transgenics.

2 Concept and Operation of Patent and Related Systems

2.1 Origins of Intellectual Property Rights

The earliest form of Intellectual Property Rights has been traced by many scholars to Venice in the Middle Ages. Master craftsmen, it seems, were beset with competition from former apprentices. To control that

competition, a law was passed that prohibited former apprentices from going into competition with licensed craftsmen for a period equivalent to the period of the apprenticeship. That period, of about 20 years, is said to be the origin of the current 20-year patent duration from first application. Certainly, craftsmen benefited from reduced competition. Apprentices benefited less so, but without the protection from competition, many may not have found masters willing to take on apprentices. Finally, the consuming public lost in the short run through higher prices, but with the long-term assurance of trained master craftsmen available to produce the products, eventually they would benefit as well.

2.2 Purposes of Intellectual Property Rights

2.2.1 Economic Justification

Over subsequent centuries, patent and related IPR laws have undergone multiple changes, but the essence of the public/private trade-off seen in long-ago Venice is still evident. Patents are temporary (typically 20 years). The inventor benefits from that period of reduced competition and thereby has an incentive to invest in inventive activities. The public benefits from the existence of products and processes that otherwise may not have existed, or whose appearance would have been delayed. The justification recognizes the copier, who does not have to recover the R&D expenses of the inventive process, can always undersell the inventor. Hence, no one outside the public sector has an incentive to invest in easily copied new products, and technological advances stagnate. Patent laws restore that incentive through the legal prohibition on direct copying.

Contemporary patent law adds a further dimension, the requirement that the invention be described. The resultant file of descriptions creates a public storehouse of technical information while helping assure competitive products can be produced soon after the patent expires. For these benefits, the public pays a higher price than would prevail in a competitive market. A higher price can come about only if supply is reduced so that the public has less of the product available than under competitive conditions. Stated differently, product use diffuses more slowly.

In addition to the mere existence of the novel product or process, the public benefits from the so-called spillover effect. Spillover recognizes that a private owner cannot capture all the benefits from a product. A large piece of property kept undeveloped by an owner not only benefits the owner but also the public, which enjoys the views and ecological benefits provided. Similarly, an invention (gasoline engine) can lead to derivative inventions (automobiles), which further benefit the public. Or the inventor, to meet unit sales and profit goals, may need to charge a lower price than many users would be willing and able to pay. Those users gain a direct benefit at the expense of the inventor.

The investment incentive is the principal justification for patents and related IPR. There is, however, another justification for patent-type laws: the provision of an incentive for firms to distribute products to other countries. Key to appreciating this aspect is a realization that intellectual property law is strictly national: protection must be held in each country to be effective. For example, a product protected in the United States has no protection in France or Japan unless specifically sought and received there. Inventors

would be concerned about unauthorized copying in those markets as well, and are typically hesitant to supply them without the corresponding intellectual property protection. Hence, intellectual property protection can assist in the transfer of products and technologies.

Patents belong to a group of related rights known as *industrial property rights*, which also include Plant Breeders' Rights, trademarks, and trade secrets. Trademarks function somewhat differently, but with a general similarity of intent. Trademarks allow owners to develop goodwill in a product with the knowledge that it will not be dissipated by unauthorized imitators. For the consumer, a trademark serves as a signal of product quality – a Coca Cola or McDonald's hamburger has a consistency and standard taste consumers expect. True Rolex watches are generally of far higher quality than the copies. Thus, with trademarks too, both the owner of the trademark and the public benefit at least to some degree.

Copyrights fall into a separate class of protection mechanisms. Copyrights are applied to creative works like books and music, although important current uses include software. Copyrights are more of a protection by right and involve fewer formal procedures.

Trade secrets impose a penalty if secrets are acquired in an inappropriate way. The secret itself may be anything of value, such as customer lists or performance records. No formal process is required to achieve trade secret status, beyond a serious effort to keep the secret that way. In that way, a trade secret can conceivably be perpetual. The formula for Coca Cola is a well-known trade secret. In many cases, firms will achieve stronger (broader) protection by combining several forms of protection within a single product. For example, a patent might protect the product, but the least cost process for producing it is protected by a trade secret. Or a product is patented while the name is trademarked.

2.2.2 Moral Justification

A second justification for IPR is a moral, or perhaps more correctly, personal rights justification. This concept, often couched in the individualism philosophy of the Enlightenment, stresses that creation (whether artistic or technical) is from the self and hence should be granted the same rights as any personal property. IPR and personal rights are aspects of the self and hence should be granted as a right. Here, the economic justification will be stressed, as it is generally. The moral right concept, though, does continue in the idea of benefit sharing as well as requirements in most patent laws that the inventor(s) be identified by name. Perhaps, the inventor does not own the invention (employment contracts, for example, typically make any invention in the course of work the property of the employer). However, he/she/they must be at least identified on the patent as the inventor.

2.3 Forms of Intellectual Property Rights Applicable to Animals

The preceding subsection laid out the general justification for IPR and identified in broad terms the major forms. This section contains more detailed descriptions of the operation of the several systems potentially applicable to animals. Greatest attention is of course given to patents.

2.3.1 Patents

Patents are intended as an incentive and reward for developing something new and

useful, but only if the development is a nontrivial extension. The system has developed specific terms and interpretations for these concepts.

Nonobviousness or inventive step: The invention should not be obvious to someone ''skilled in the art.'' This is the nontrivial requirement.

Novelty: The invention must be new in the sense of not having been previously known through publication or public use. The United States uses a system with a one-year ''grace period,'' which means simply that the invention could have been revealed up to one year prior to applying for a patent. Most countries do not allow any prior revealing of the invention – in what is known as absolute novelty. Absolute novelty, in particular, is difficult for public sector researchers whose work often requires publishing of results.

Utility: Utility requires that the invention must serve some identified purpose. This does not say the invention must be practical – patent offices do not judge practicality. Rather, the requirement is that a use be identified. This is an important component of the system for it led to the rejection of applications for human genes early in the Human Genome Project. Those applications read to a gene only, with no specific knowledge of a use for it. Hence, the rejection.

Issued patents are all of the same general type, although this masks some large differences. One is the *scope* of an individual patent – a wider scope means a related product must be more different so as not to be infringing. The scope of the first animal patent, the ''Harvard'' mouse, is quite broad, reading in the first claim, ''all non-human mammals'' that exhibit the identified trait. Often, patents in new technical fields are broad, narrowing as the techniques become more standardized. Typically, a person knowledgeable in the field is needed to interpret the scope of a patent.

A second distinction is made on whether the patent may be referred to as *per se*, process, product by process, or dependent. Those are not terms that will appear on the patent, but can be inferred from a close reading. For example, a claim which reads ''a means of'' is usually a patent for a process. A product by process patent covers the product only if it is produced in the described way. A different production technique lies outside the patent. The concept of *per se* and dependent patents can be explained by a factitious reference to aspirin. Imagine the initial aspirin patent was for headache relief (in fact, it was a natural product with a patent for a chemical synthesis). Because (in this example) it was the first, the patent owner had rights to any subsequently developed uses. One was identified – the use to help prevent and subsequently recover from a heart attack due to the blood thinning property – and patented. The later patent though is dependent on the first one, so it cannot be used without the permission of the initial patent owner. The owner of the initial patent, for his or her part, also cannot use the improvement without permission. Often, what could be an impasse is resolved with a cross-license between the two owners.

2.3.2 Plant Breeders' Rights

Plant variety protection (PVP) is a special purpose system only for plants. Technically, it is a form of *sui generis* or special purpose system owing to the exclusive focus on plants. Plant breeder's rights (PBR) are quite recent, with origins in the 1930s and 1940s. UPOV (the French acronym

for the International Convention for the Protection of New Varieties of Plants), the international convention, was established only in 1961.

PBR replaces utility, nonobviousness, and novelty for patent systems (see above) with uniformity, stability, distinctness, and novelty (abbreviated as DUS). Novelty is the same in concept to patents, although the specific terms and use conditions differ. Uniformity and stability are technical requirements, which assure that the protected variety is identifiable after repeated multiplications. Clearly, if the protected product (variety) cannot be definitively identified, the system breaks down. For the future, genetic markers or a related technology may be used, but that is not the case at present.

Distinctness is akin to nonobviousness for patents. Distinctness may be claimed in one of a number of traits, such as disease resistance or flower color. Most countries actually grow out varieties and measure the difference from a base or reference variety. In the United States, the claims of the applicant are generally accepted, akin to a registration system. Moreover, the US Plant Variety Protection Office allows distinctness for traits of no practical merit. Hence, PBR in the United States are generally considered to be weaker than in other UPOV-member countries.

PVP have other components, which mean that they provide weaker protection than patents. These are the so-called Breeders' Rights and Farmers Privilege. Breeders' Rights specifically allow breeders to use protected varieties in a breeding program without the permission of the variety owner. For patented products, this is known as the *research exemption*. Because the research exemption is not statutory (written in the law), it is a matter of court interpretation, the focus of which is still under debate by scholars and practitioners. The Farmers Privilege expressly allows farmers to retain the crop for use as a seed source for a subsequent crop. The farmer, however, may not sell the seed or share with other farmers. The most recent UPOV Act (1991) makes the Farmers Privilege a national option, but most countries (including the United States) are choosing to allow it. In Europe, with the exception of ''small farmers,'' a payment for seed savings set at 50% of the ''normal'' license fee must be paid.

PVP are intended to protect the entire plant as well as its propagating parts (seeds, etc.). This is in line with the specific focus of preventing direct competition for that variety. A weakness became apparent when overseas growers (where PVP was unavailable) shipped plant parts such as flower blossoms into a protected market. That was not illegal until the most recent version of PVP legislation was adopted, extending protection to plant parts, and potentially to products of those parts (say oil from a protected soybean variety).

For biotechnological applications though, the current scope of protection is insufficient. Breeders can simply use crossbreeding or other means to transfer a genetically engineered gene construct from one variety (protected) to another (unprotected). The breeders' rights exemption makes such a transfer perfectly legal. A patent plant would provide protection for it would read to the genetically engineered trait, so protection would not be voided through the breeding process. Moreover, the breeding process itself would be a likely infringement. Conversely, PVP covering the variety and a patent for the gene construct provides protection similar to a patented plant.

PVP-like systems have two advantages for animals. They are simpler and less

costly to secure, and hence appropriate for sequential improvements such as livestock breeding. Second, many countries have specifically prohibited patents for plants or animals but are allowing PBR systems. However, a workable system requires identifying the target population – in short, a workable definition for a ''variety.'' This exists for plants, but the relatively small number of progeny and inherent heterogeneity of an animal line (with the possible exception of inbred experimental lines) make a direct extension of PVP to animals inappropriate. One proposal for an ''Animal Breeders' Rights'' system is described in Sect. 3.4.

2.3.3 Trade Secrets

Since the 1930s, corn breeders have used trade secrets to protect first generation (F-1) hybrids. Since hybrids do not reproduce true-to-type, the sale of seed does not allow the duplication of the seed. Breeders need only protect the pure lines and crossings used to gain *de facto* protection of the resultant hybrid. Hence, breeders typically fence their pure line fields and of course do not reveal the crossing sequence.

For agricultural livestock, a similar approach is used by poultry and hog breeders. There, multiple crosses of pure lines produce synthetics with characteristics similar to plant hybrids. Poultry breeders keep tight control of their pure lines and release grandparent and even parent stock only under careful supervision. Of course, this strategy is not applicable for traditionally crossbred animals.

3 Issues with Protecting Living Organisms

The preceding text describes the general considerations for protecting inventions. Living organisms though bring to bear several additional considerations. This can be inferred from the general recentness of extensions of protection to living matter. An early example is a patent granted to Pasteur in the 1880s for a yeast strain, but the Patent Office seemingly considered the product to be inanimate rather than animate. The initial specialized law was the (US) Plant Patent Act of 1930 (subsequently incorporated into the Patent Act). The Plant Patent Act applies only to asexually propagated plants. Asexually propagated materials are stable, thus ending congressional uncertainty about the identification of protected materials over repeated regeneration.

Subsequently, European interests took the lead in protecting plant varieties, beginning in the 1940s. The first international convention, UPOV, was adopted in 1961 with the most recent version dating to 1991. The United States did not adopt a version, the Plant Variety Protection Act, until 1970, which was amended in 1980 and 1994.

3.1 Developments in the United States

Of major significance was the 1980 Supreme Court decision in *Chakrabarty*. While the particular decision related to a microorganism (for more rapid decomposition of spilled crude oil), the decision was made in sweeping terms. The Court declared, ''everything under the sun that is made by man'' is patentable subject matter. Shortly thereafter, in 1985, the patent and trademark office (PTO) in an internal decision, *Ex parte Hibberd*, declared (higher) plants to be patentable subject matter. ''Patentable subject matter'' simply means that the application cannot

be rejected solely because of the area of application.

Interestingly, in 2001, there was a challenge heard by the Supreme Court to the provision of patents for plants (*J.E.M. AG Supply v. Pioneer Hi-Bred*). The challenge began (in typical fashion) as a defense for an infringement charge, declaring there was no infringement for the patent was invalid. The reason? The Congress passed the PVPA to protect plants and hence did not intend to allow for the extension of patents. The Supreme Court strongly endorsed *Hibberd,* declaring that patents and PBR could ''mutually coexist.''

Two years after *Hibberd,* in another internal decision in *Ex Parte Allen* (1987), the PTO declared higher animals to be patentable subject matter. Interestingly in that case, the underlying application for a ''polypoidal'' oyster was rejected for insufficient nonobviousness. The first animal patent was not issued until April 1988 for the ''Harvard mouse,'' a laboratory research specimen.

3.2 Developments in Europe

Patent protection for animals (as well as other forms of living organisms) in Europe has been shaped first by the wording in the European Patent Convention (1973) (EPC), which, in Article 53(b), prohibited patents for ''plant or animal varieties or essentially biological processes for the production of plants or animals.'' With an origin dating to an earlier and simpler era, it is now, with the advent of the new biotechnology, no longer easily determinable what is an ''essentially biological process.'' Within Europe, there are two separate routes to patents: through national patent offices or through the European Patent Office (which grants ''bundled'' national patents). While there are small technical and practical differences between the patents received from the routes, the legislation harmonizing the requirement of the Convention means that the two systems operate in parallel for purposes here.

To clarify the interpretation of the phrase ''essentially biological,'' the European Directive on the Legal protection of Biotechnological Inventions (Directive 98/44/EC, Rule 23(b)(5)) contains the definition:

''A process for the production of plants or animals is essentially biological if it consists entirely of natural phenomena such as crossing or selection.''

As a consequence of that Directive, animals (and plants) that have been transformed genetically are patentable subject matter. Relevant Directive articles are as follows:

- Biological materials isolated from its natural environment or produced by means of a technical process may be the subject of an invention even if it previously occurred in nature (Article 6.3).
- The protection conferred by a patent on a biological material shall extend to any biological material derived from that biological material through propagation or multiplication in an identical or divergent form and possessing those same characteristics (Article 8).
- The protection conferred by a patent on a product containing or consisting of genetic information shall extend to all material (except the human body) in which the product is incorporated and in which the genetic information is contained and performs its function (Article 9).
- The protection shall not extend to biological material [] where the multiplication

or propagation necessarily results from the application for which the biological material was marketed, provided that material is not subsequently used for other propagation or multiplication (Article 10).

Note that, as a consequence of the genetic transformation, the products are no longer potentially construed as ''discoveries,'' and hence are specifically unpatentable (EPC Article 52(2)(a)). Stated differently, an animal (or plant) is patentable in Europe (provided other patenting requirements are met) if the invention applies to more than the single variety.

The ''Harvard mouse'' invention, first to receive a US patent, also received the first animal patent in Europe, but the path was less than direct. The initial application (1985) was dismissed (1989) on the interpretation that it was a prohibited animal variety and then granted on appeal (1990, issued 1992). A subsequent opposition (1992) did not lead to a cancellation, but the revised patent was limited to rodents only (2001). Further appeals are likely.

The EPC (Article 53(a)) further allows exclusions from patentability for inventions that would be contrary to ''ordre public'' or ''morality.'' Some attempts, generally unsuccessful, have been made to identify animal patenting as immoral. The Patent Office applies a test contrasting the public benefit from a successful invention with the potential suffering of the animals involved. Specifically, the Examining Division declared:

''In the case at hand three different interests are involved and require balancing: there is a basic interest of mankind to remedy widespread and dangerous diseases, on the other hand the environment has to be protected against the uncontrolled dissemination of unwanted genes and, moreover, cruelty to animals has to be avoided. The latter two aspects may well justify regarding an invention as immoral and therefore unacceptable unless the advantages, i.e. the benefit to mankind, outweigh the negative aspects.''

3.3 Legislation in Other Leading Countries

Many patent statutes are silent on the patentability of higher life forms, making the patentability of animals a matter of legal interpretation. This point aside, 17 countries have granted the ''Harvard mouse'' patent (Austria, Belgium, Denmark, Finland, France, Germany, Greece, Ireland, Italy, Luxembourg, The Netherlands, Portugal, Spain, Sweden, the United Kingdom, and the United States; plus Japan has a related patent and New Zealand has issued a patent for another form of transgenic mouse). The issues in notable countries outside Europe and the United States are described below:

Australia: The Patent Office does not treat higher life forms (including animals) distinctly from lower life forms. And since lower life forms that are novel and inventive are patentable, it may be (and has been) higher animals can be patented too.

Canada: The ''Harvard mouse'' patent was initially rejected by the examiner on the grounds that higher life forms were not patentable subject matter in Canada. Following were a series of appeals:

- 1995 appeal to Commissioner of Patents, which upheld examiners rejection on the grounds that the creation of the mouse proper was controlled by the laws of nature.
- 1998 appeal to Trial Division of the Federal Court, which upheld the Commissioner's interpretation that higher

life forms were not patentable subject matter in Canada.
- 2000 appeal to the Federal Court of Appeals, which overturned the Trial Division decision, drawing on the reasoning of the US *Chakrabarty* decision.
- In 2002 (May), Commissioner of Patents appealed to the Supreme Court of Canada.
- In 2002 (December), the Supreme Court of Canada decided 5 to 4 that higher life forms are not patentable in Canada. The details are given below.

The sole issue before the Supreme Court was that the patentability of life forms constitute a ''manufacture'' or ''composition of matter'' within the context of Article 2 of the Canadian Patent Act. Interpreting the terms ''manufacture'' and ''composition of matter,'' the former was understood to be a ''nonliving mechanistic product or process,'' while the latter was construed, in the context of the proceeding terms of allowable subject matter (invention), ''any new and useful art, process, machine, manufacture or composition of matter'' (Patent Act, Section 2). The majority concluded that, while ''composition of matter'' can be interpreted broadly, the context of Section 2 means it is ''best read as not including higher life forms.''

''Higher life forms cannot be conceptualized as mere 'compositions of matter' within the context of the *Patent Act*. [] It is possible the Parliament did not intend to include higher life forms in the definition of 'invention.' It is also possible the Parliament did not regard cross-bred plants and animals as patentable because they are better regarded as 'discoveries.'''

The decision proceeds to note that patents for human life cannot be excluded judicially by the courts and that the existence of Canadian PVP legislation can be interpreted as possibly indicating the need for separate legislation to apply to higher life forms generally. Overall, ''clear and unequivocal legislation [by the Parliament] is required for higher life forms to be patentable.''

New Zealand: New Zealand uses the same term ''manner of manufacture'' to describe patentable subject matter as does Australia, so that applications in the two countries have progressed in parallel. Specifically, New Zealand has granted patents for higher animals.

Japan: Part VII of the Examination Guidelines for Patent and Utility Model in Japan (2000), Chap. 2, Part 4 describes when patents may be awarded for animals (Available at (verified 4/5/04) http://www.deux.jpo.go.jp/cgi/search.cgi?query=examination+guidelines&lang=en&root=short). Patents may be granted *per se,* for parts of animals or methods of creating animals. Humans are excluded. Also excluded are discoveries and those inventions not capable of industrial application (utility).

3.4 International Agreements

This European Patent Convention wording is also significant because it has carried through in modified form into the TRIPs (Trade-Related Aspects of Intellectual Property Rights) of the 1994 World Trade Organization. Signatories (all 147 of them currently) have agreed to adopt certain minimum forms of intellectual property protection. Some are straightforward – the provision of trade secret legislation is an example. The area of plants and animals though remains ambiguous, for in Article 27.3(b), countries have the option of excluding from patentability ''plants and

animals other than microorganisms, and essentially biological processes for the production of plants or animals []. However, Members shall provide for the protection of plant varieties either by patents or by an effective *sui generis* system or by any combination thereof.'' While the situation in some developed countries is ambiguous regarding the patenting of animals, as is noted above, virtually all developing countries are choosing to prohibit patents for plants and animals. In this case, the bar to the patenting of animals is more absolute than under the European Patent Convention for the wording reads as ''animals,'' not ''animal varieties.'' In consequence, it will likely be some time at best before animals are patentable in developing countries.

It is worth noting that while there is extant a form of *sui generis* (which means ''special purpose'') protection for plants in the form of PBR (see Sect. 2.3.2), nothing of the type exists for animals. Its absence means that there is no protection for animals not qualifying for a patent, which is to say nontransgenic animals. Yet the development of superior breeds is a costly and risky endeavor, just like other inventive activities, so animal breeding can be presumed to be under-funded as a consequence of the absence of a *sui geners* protection system. Lesser has attempted to conceptualize such a system, noting that the principal complexity is any workable definition of an ''animal variety.'' Some animal lines such as those typically used in experimentation are sufficiently inbred to be stable and describable. Typically though, livestock, insects, fish, and pets are sufficiently heterogeneous as to defeat the description requirement of an IPR system. Further compounding the issue is the simple operation of heredity, which shows that only half the offspring of a simple trait will inherit the trait if just a single parent is a carrier, while more complex traits are inherited at far lower levels of probability. As a result, without testing individuals there is no assurance as to which will and which will not inherit a trait.

Lesser's approach in bypassing these characteristics of many higher animals functions more like a trademark than patent or PBR law. That is, protection is applied to the name of a parent and royalties are owing if the name is evoked, but not otherwise. Hence, one of *Man O'War's* foals would be charged royalties if he were specifically identified in a blood line, but not otherwise. Many beef cattle and purebred dogs use similar systems of identifying parent(s), while chickens and some fish and hogs (known as *synthetics*) are biologically more like hybrids than traditionally bred animals. They can be effectively protected through trade secrecy (see Sect. 2.3.3) by keeping the patent pure line stock and crossing sequence as confidential.

4 Issued Patents

On-line search engines of patent files at the US Patent and Trademark Office and the European Patent Office (EPO) make it possible to determine the numbers and types of patented animals. There is some uncertainty in the counts for it is not always entirely clear if the patent reads to an animal or a method for producing one. Also, when considering the species of the animals, some are definitive while other patents read to several species or all ''nonhuman mammals.'' Nonetheless, from a review of patent files, it is possible to gain a clear understanding of the kinds of patents and uses thereof.

4.1
Animal Patents in the United States

US animal patents are classified in US class 800/13 – 20 (available at www.uspto.gov under patents, search). As of mid-2004, animal patents comprised:

Mammal (800/14)	88
Bovine (800/15)	22
Sheep (800/16)	21
Swine (800/17)	24
Mouse (800/18)	350
Bird (800/19)	1
Fish (800/20)	9

It is clear that mice (and rats) are the most commonly patented. As for the uses, animal disease models (as with the initial ''Harvard mouse'') dominate. An example is patent # 6,156,279, *HIV transgenic animals and uses therefore*, Dec. 5, 2000, which first claim reads (claims identify the invention):

1. A transgenic rat, whose genome contains at least one copy of a human immunodeficiency virus type 1 (HIV-1) proviral DNA [] and wherein said rat develops at least one symptom of acquired immune deficiency syndrome (AIDS).

Second in number are patents for the use of transgenic animals to produce useful compounds, most of which are excreted into milk. An example is patent # 6,727,405, *Transgenic animals secreting desired proteins into milk* (April 27, 2004):

1. A non-human mammal whose genome comprises a DNA construct [] wherein said mammal is selected from the group consisting of mouse, sheep, pig, goat and cow, and wherein said heterologous protein is expressed in the milk of the mammal.

Further in the medical area is a patent (# 6,331,658, *Genetically engineered mammals for use as organ donors*, Dec. 18, 2001) for producing a transgenic pig as a source of human transplant organs with a reduced likelihood of rejection:

10. A non-human transgenic mammal, wherein the genome of the mammal stably includes a nucleotide sequence [] such that the organ exhibits a decrease in antibody-mediated rejection. . .
11. The mammal of claim 10 wherein the mammal is a pig.

Examples of nonmedically related inventions are less common. One is (H1,065, Apr. 30, 2002, *Transgenic avian line resistant to avian leukosis virus*):

1. A chicken line, derived from a strain of chickens which is susceptible to avian leukosis virus infection, which chicken line has integrated in its genome a proviral sequence [] and is thus genetically resistant to avian leukosis virus, subgroup A.

This invention appears to anticipate commercial use, viruses being a cause of significant loss in poultry production.

Also included are – interestingly – transgenic pets. Led by patent # 6,380,458 (Apr. 30, 2002) is *Cell-lineage specific expression in transgenic zebrafish*. The claims leading to the commercial product, ''GloFish,'' are:

1. A transgenic zebrafish that expresses a heterologous expression product, comprising a zebrafish cell lineage-specific expression sequence. . .

4. The transgenic zebrafish of claim 3 wherein the reporter protein is green fluorescent protein.

4.2 Animal Patents at the EPO

Animal patents (see Sect. 3.2) are indeed being issued in the EU. The UK Patent Office issued patent number GB2382579, ''Assays and Disease Models Using Transgenic Zebrafish,'' in October 2003. The animal model screens suppressors that lessen the activity of a disease gene.

Current applications number approximately 70 (although not all can be expected to mature to a grant). Animal model patents represent 55 of applications, and expressions of proteins the remainder. The pattern is similar to the United States, and indeed many applications are based on inventions for which the first application was made in the United States. Examples from European inventors include:

''Transgenic Animal Model for Obesity Expressing FOXC2.'' Publication # EP1255774 11/02.

''C1 Inhibitor Produced in the Milk of Transgenic Mammals.'' Publication # 1252184, 9/01.

5 Issues with Patented Animals

This section addresses the numerous issues that arise or are associated with patented animals. The list of items includes other technical developments that are potentially patentable but have yet to be the subject of applications to what is known of effects, environmental, economic, and social, to attitudes.

5.1 Status of Technology

The current granted patents and applications (see Sect. 4) clearly indicate technologies and applications at a high level of development. It is possible that developments that are generally either (1) not sufficiently refined or novel to be the subject of an application, or (2) are of insufficient economic potential to justify the costs associated with a patent are absent. Yet, those technologies may in future years mature to become the subject of applications and so are worthy of notice. A technology of particular note is the replacement of microinjection (first applied in 1981) and retroviral vector systems (1985) as the transformation methods of choice to the use of sperm-mediated transgenics, or techniques involving nuclear transfer. Microinjection, while functional, was marked by a low level of success (less than 1%). That level means successful transformations are costly, and potentially contributes to unintended animal suffering.

Transgenic animals are produced for five underlying reasons:

- Improve animal health
- Increase productivity and improve product quality
- Mitigate environmental effects of animal production
- Produce therapeutics
- Provide models for medical research.

As is readily seen in Sect. 4, the final two reasons dominate current patents, while the first is also in evidence. The first three listed are nonetheless underrepresented in current patent documentation, and so warrant further attention here.

Sample developments are reported in Table 1.

Tab. 1 Examples of developments with transgenic animals.

Species	***Modification***	***Purpose***	***Main beneficiaries***
Tilapia	Growth hormone	Faster growth	Fish farmers
Salmon	Growth hormone	Faster growth	Fish farmers
Salmon	''Antifreeze'' gene	Faster growth	Fish farmers
Sheep	Antibody in milk	Enriched milk	Consumers
Cow, ewe	Human protein in milk	Produce molecules	Humans
Cow	Higher casein	Enriched milk, heat resistance	Food industry
Pig	Phytase gene	Reduce phosphorus in excrement	Environment
Insects	Male sterility	Reduce pest populations	Farmers, public
Mosquitoes	*Plasmodium* (malaria) resistance	Health	Humans, esp. in tropics

Source: Findinier 2003, pp. 20–21.

A few of these require further explanation. Food quality/composition is a highly desirable development, but technically it has been difficult to achieve as traits are frequently controlled by multiple genes. Plant biotechnology has experienced similar complexities. Fish biotechnology is largely directed to enhanced growth rates, using several distinct approaches. Transgenic salmon have exhibited growth rates three to five times the nontransformed controls. Those with the antifreeze attribute show growth throughout the year, not only during the warmer months.

The transgenic Enviropig© uses the phytase enzyme transferred from a bacteria to help with the digesting of phosphorous in cereal grains. There is an 80 to 100% percent improvement over the figures for nontransformed pigs in the sense that there is no need for phosphorous supplements; Further, there are reductions of 57 to 64% of phosphorous in manure. Owing to the effect of phosphorous on stimulating aquatic algae growth, its reduction in manure will have distinct environmental benefits. However, the transgenic must compete in the marketplace with feed-based phosphorous-reducing approaches, so the practicality remains to be proven.

Genetic male sterility to control pest populations is seen as a more cost-effective alternative to radiation sterilization. It has the conceptual benefit of not reducing the competitiveness of the sterile males, but practicality varies across species because of the ease of sexing and degree of monogamous mating. Mosquitoes resistant to *Plasmodium* provide an alternative approach to controlling one of the greatest causes of loss of life worldwide. The need is greatest as populations are developing resistance to available prophylactic medications. However, studies have shown that resistance has to be near 100% to be effective, and resistance-delaying strategies may mean the engineering of multiple gene resistance, a complex and time consuming task.

5.2 Benefits

The preceding sections describe – or, at minimum, hint at – the benefits generated

by patented animals. In this section, we have included further documentation of the benefits that are being generated and to whom they accrue.

5.2.1 Animal Models

Numerous animal models are being developed through the mechanism of biotechnology. Firms are presently designing new models on request, as with Charles River Laboratories, one of the large supplier firms:

> Charles River and Xenogen Biosciences formed a marketing collaboration []. Xenogen Biosciences provides custom programs for the development of transgenic animals []. (www.criver.com; verified 5/04)

Products are in considerable demand. By 1989, orders for the path breaking ''Harvard mouse'' amounted to 10 000 at $50 each, versus $3.50 for standard lines.

5.2.2 Production of Compounds

The actual production costs of compounds using transgenics versus traditional approaches are not publicized, making direct comparisons impossible. However, complex compounds are very costly to produce using bioreactors, such as blood clotting Factor IX, which costs $100 000 to 200 000 annually per patient for hemophiliacs. Pigs can secrete Factor IX into milk at a concentration 250 to 1000 times the level of bioreactors, making purification simpler. Indeed, production is so elevated that only several hundred transgenic pigs are needed to supply all hemophiliacs worldwide. Animal numbers, however, will be so small compared to standing herd sizes as to have no effect on the farm and agribusiness sectors.

5.2.3 Other Applications

Other transgenic technologies, and particularly those used for milk production, are insufficiently commercialized at this stage to have any reliable indication of effects on producers or consumers. One can however note that animal diseases are a major cost component for prevention, treatment, and associated losses so that enhanced resistance would have marked benefits for both producers and consumers of animal products. For example, US vet and medicine costs for hogs per hundredweight of gain in 2002 was $1.10, or 2% of total costs, but 14% of residual returns minus operating costs. Worldwide, small farmers are the major owners of livestock – in India, they own 70% of the livestock but just 30% of the land area – and could be a major beneficiary.

For fish, a genetic mutation (nonbiotech) leading to genetically male Nike tilapia increased production by 30%. For Philippine farmers utilizing them, the net income doubled.

5.3 Areas of Concern

Animal patents are, to understate the current situation, very controversial, at least with certain groups. Concerns are focused on

- ethics,
- food safety,
- health,
- environmental safety, and
- access to patented animals.

Here the underlying positions will be summarized in reverse order. No attempt is made to represent a consensus position as that may not exist, or is not discernible. Rather, in the following section, attitude surveys from several countries are reported

as an indication of the acceptability of patented animals in particular, and the products of those creations.

5.3.1 **Access to Patented Animals**

Effective access involves a complex of cost, availability, and use provisions. Here, attention is on agriculture/aquaculture and other dispersed uses rather than medical applications, where commercial channels among limited number of users are of long-standing nature.

Cost cannot be reliably projected at this stage, other than to note that most food production have low margins, meaning high process would render the innovations uncompetitive in many cases. For example, with rBST, an injected biotech product used for stimulating milk production, analysis suggests that the supplier, Monsanto, prices the product near the breakeven point for users. That keeps adoption rates low – indeed, over time, use has been declining. Distribution of livestock-based technologies depends in part on the production rates by species. Poultry are high producers, hogs medium, while cattle naturally produce but one calf annually. For single gene traits, only half will inherit; for multiple gene ones, less. Embryo splitting and implantation speed up the rate, but at considerable cost. For cattle, then, dissemination through herds will be a slow process.

A second consideration relates to the collection of royalties, assuming that producer cash flow considerations will dictate royalties be paid when returns are realized at sale time. Lesser's analysis proposes that packing plants (livestock) or breed associations (pets) will be the royalty collectors of necessity. Until rapid, cheap tests are developed to determine the presence of traits, fees must be based on herd averages.

5.3.2 **Environmental Safety**

Environmental safety applies principally to concerns over the escape and competition by transgenic animals in the natural environment. Competition can affect the same species through crossbreeding, or other species by colonizing an environmental niche. The degree of the threat then depends in large measure on a species' ability to become feral, escape from captivity, and its mobility. Insects then are predicted to have substantial potential for environmental damage while domesticated cattle are ranked low (Table 2).

Some experience exists with nontransformed salmon raised in cages in the sea. Escapes are estimated at 15%, a number confirmed by the percent of farm-raised salmon caught by Norwegian fishermen. However, farm-raised salmon, like most nonnative species, have been found to be ineffective breeders compared to the wild stock. Nonetheless, if the alien species is a large portion of a local population, then a notable impact can be anticipated.

Procedures for assessing and, when needed, mitigating the environmental

Tab. 2 Environmental risk factors levels for transgenic animals.

Animal	*Ability to become feral*	*Likelihood of escape*	*Mobility*
Insects[a]	High	High	High
Fish[b]	High	High	High
Rodents	High	High	High
Cats	High	High	Moderate
Pigs	High	Moderate	Low
Rabbits	High	Moderate	Moderate
Chickens	Low	Low	Low
Cattle	Low	Low	Low

[a] Gypsy moth and African bee only.
[b] Excludes shellfish and crustaceans.
Source: FDA, reported in Findinier 2003, p. 17.

affects of transgenics are known as *biosafety*. (The term sometimes encompasses food safety, but as used here refers to environmental aspects only). National legislation specifies the review procedures involved, although they are better developed and more practiced with plants than animals. Internationally, there is an umbrella agreement, the Cartagena Protocol under the Biodiversity Convention (available at http://www.biodiv.org/biosafety/default.aspx; verified 5/04). The Protocol, established in 2000, has to date (5/04) been ratified by 98 countries. It establishes general procedures and requirements but does not contain specific provisions.

5.3.3 Health

Human health issues are associated with the development of new viruses, particularly if animal organs are used for human transplants. A retrovirus used as a transformation vector could combine with a latent virus in the new host, spreading through the food chain and into humans. This threat can be ended by discontinuing viral vectors.

Transplanted organs present a special risk for the same genetic modification that reduces the rejection of the foreign organ could also weaken the patient's immunity to the new virus. Thus situated, the new virus could adapt itself to the novel human host environment and become infectious. This possibility is not trivial for pigs – already the subject of a xenotransplantation patent (see Sect. 4.1) – have at least six known endogenous retroviruses. Overall, concerns about the generation of new diseases "require a chain of events of very low cumulative probability but for which there are some experimental precedents."

5.3.4 Food Safety

Internationally, food safety standards and procedures are established under FAO/WHO by the Codex Alimentarius Commission. The main purposes of this program are protecting health of the consumers and ensuring fair trade practices in the food trade, and promoting coordination of all food standards work undertaken by international governmental and nongovernmental organizations.

In 2003, the Commission adopted the "Principals for the Risk Assessment of Foods Derived from Modern Biotechnology" as an overarching agreement for understanding risk assessment and nutritional status of foods derived from biotechnology, including transgenic animals (available at http://www.fao.org/es/ESN/food/risk_biotech_taskforce_en.stm; verified 5/04). The principals are based on the following elements:

- Premarket assessment on a case-by-case basis
- Assessment based on a comparison with traditional foods (known as substantial equivalents)
- Risk management should be proportional to identified risks.

Food concerns of transgenic animals are focused largely on the existence of novel proteins. Those proteins can be added intentionally (as with a growth hormone), result from unanticipated compositional changes, or may be a consequence of the unpredictable trans gene expression in animals. For example, there may be a transfer from mammary glands to the blood and hence into the food supply. When testing for food safety, the traditional focus is on

- toxicity,
- allergenicity, and
- whole food value.

Toxicity is relatively straightforward to examine, although there is always a policy decision over which populations (elderly, children) are to be protected and at what presumed consumption levels. Allergenicity is problematic to screen for because very small portions of a population may be very allergic to a wide range of proteins. Whole food value – an assessment if the total nutritional balance has been altered – presents test complications because the subject product often constitutes a small portion of the diet so that feeding large-enough amounts to detect nutritional effects would be unfeasible or unhealthy. In any case, similar issues arise with transgenic plant-derived foods, and to date there is no documented example of any deleterious human health effects.

5.3.5 **Ethics**

Individuals may object to patenting animals either directly on the basis of a rejection of ownership and ''playing God'' by interfering with a natural creation or indirectly because patents can foster actions or behavior considered deleterious to animals. The first point is a difficult one for multicultural societies to resolve because opinions can be intense, but may vary widely. What is morally repugnant to some may be fully acceptable to others. The best indication of the prevalence of these objections is public opinion surveys (see Sect. 6 following).

The indirect effects of patents through transgenics can be discussed in the terms of animal rights and animal welfare. Animal rights supporters may be concerned with, for example, not changing what is essential about a pig, or allowing animals to live in a way consistent with their nature. Pigs, for example, are both social and programmed to rooting and, by one perspective, should not be prevented from those expressions. What is innate to a species is often difficult to conceptualize after millennia of being subject to human control. And rights have broad consequences that are likely not fully comprehended by many.

Animal welfare, however, has wide and growing support, largely directed to the avoidance of unnecessary suffering. Austria, for example, recently adopted legislation specifying that chickens must be reared on a floor (not in cages) and Dobermans may not have tails and ears trimmed for appearance reasons. Animal suffering is a possible issue with animal patents if, for example, territorial instincts can be reduced, allowing for more dense confinement, or if experimentation leads to suffering. How is that matter addressed?

A partial offset to overall suffering is the possibility of experimentation that will lessen future suffering. Developing disease treatment or resistance is an example. There are examples of disease-resistant animals becoming available (see Sect. 4). Yet, many experiments will benefit humans far more than the test species. In those cases, a common approach is to consider the balance of (animal) suffering compared to potential (human) benefit. In Europe, the EPO has devised a process for determining if the advantages outweigh the negative aspects (see Sect. 3.2). Outside patent offices, calls have been made for weighing ''costs and benefits.'' For the foreseeable future, the utilitarian view of placing human needs in the primacy while minimizing the costs to animals seems likely to prevail, but views of animal rights are expanding with the general public and

could affect fundamental research with transgenics in the longer term.

6 Public Attitudes

As a background, it is important to recognize that the general public is not particularly well informed about biotechnology. As examples:

- 1999 (Gallup) 50% heard little/nothing
- 1987 (Gallup) 63% heard little/nothing
- 2001 ''heard a great deal about genetically modified foods'' – 44%
- 2003 ''heard a great deal about genetically modified foods'' – 34%

If anything, awareness in the United States is declining in an era where there are no notable headlines regarding transgenics.

Indeed, the public indicates a low level of knowledge on the subject – in 2001, respondents self-selected a median rating of only 3 (1–10 scale of ''knowledgeable'') – and demonstrates a limited knowledge with such replies as:

United States	33% believe tomatoes do not contain genes, 58% say they have not eaten transgenic foods
Europe	65% believe tomatoes do not contain genes

Of course, knowledge does not necessarily influence opinions, which are based on emotions. If anything, a lack of knowledge makes would-be consumers less accepting as risk is associated with the new. For that reason, more educated consumers, who presumably are better able to educate themselves, typically are more accepting. The lack of knowledge does make respondents especially vulnerable to differences in terminology. Surveys have indicated that the label biotechnology is better accepted than using ''genetically modified.'' Hence, traditional supporters of biotechnology like food companies use the former in surveys, while opponents such as some environmental groups favor genetically modified. Overall, as always, surveys should be interpreted with some care.

6.1 Attitudes in the United States

Whatever the comfort level with eating transgenics, consumers are accepting the transforming of life forms for other reasons. While transgenic animals for food are ranked at 2.8 out of 10 (compared with 6.8 for plants), other uses of transgenic animals is less than half that level, or 2.3 (Fig. 1). Seemingly, the closer the life form is to direct human experiences, the lower the acceptance.

Support for transgenic animals is thrown into sharper contrast when evaluated against transgenic plants. For plants, there is an 81% positive position, and a 67% point spread between favorable and unfavorable views (Fig. 2). For the same question applied to animals, the figures are 49% approval and only an eight-point spread. When the issue is less cost and more specific health and safety benefits, the divergence is smaller, but still notable. For example, 57% of respondents favor the use of animals for transplant organs, while 58% support the idea of producing spider-web compounds in goat milk (which can make strong and light bulletproof vests). Another survey reports the approval for plant transgenics of 49% in 2003 versus 27% for animals.

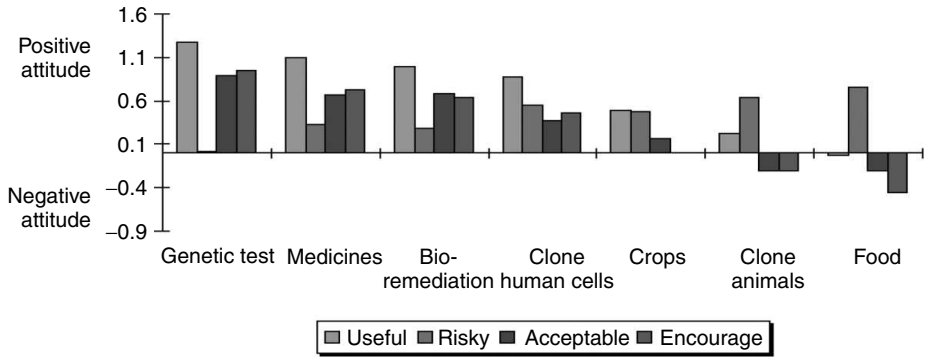

Fig. 3 European attitudes to uses of biotechnology, 2002. *Source*: Nature America, 2000, from Eurobarometer.

These opinions should be viewed in the context of public knowledge of animal biotechnology. In fact, 32% of Americans state that they do not know enough to form an opinion on the subject and another 11% are neutral (28% have a favorable impression, 29% unfavorable). Consumers distinguish among three areas of animal biotechnology. They are favorably disposed (55%) toward ''genomics,'' the use of genetic information to improve animal care and food quality from animals. However, fewer consumers are favorably disposed toward genetic engineering in animals (36%), and even fewer toward cloning (18%).

6.2 Attitudes in Europe

While Europeans are more opposed to biotechnology than are North Americans, attitudes are nuanced by the use of the technology, as in North America. Support is far higher for medicines than food in general (Fig. 3).

By 2002, the periodic Eurobarometer series on attitudes to biotechnology had added a question about xenotransplantation, the only question with direct relevance to patented animals. The absolute rating was similar to crops, with useful and risky at nearly identical levels (Fig. 3). Weak support exists in 13 of the 15 countries polled, with Greece, Finland, and Austria in opposition (Table 2).

The question if there is a general change in attitude over time cannot be answered directly from the opinion surveys because of changes in the wording of the question. However, partitioning the respondents into supporters and risk acceptors, a general pattern of increases in support for ''GM foods'' is evident in all countries but France, Italy, and the Netherlands. Indeed, support in Italy actually declined – the only country where this happened.

Keywords

Anomalous scattering
If the wavelength of the incident X-ray beam is around the absorption edge of a given atom, its atomic scattering factor becomes complex with a normal, a dispersive, and an absorption component.

Atomic scattering factor
Mathematical expression for the X-ray scattering of an individual atom.

Crystallographic R-factor
Reliability factor for the X-ray structure determination, sum over the absolute values of the differences between the observed and calculated structure factors divided by the sum of the absolute values of the observed structure factors.

Electron density function
The spatial distribution of electrons in the crystal, which can be obtained by the Fourier transformation of the structure factors, represents the atomic arrangement in the crystal.

Ewald construction
Construction to visualize the diffraction of X-rays by a crystal; a sphere with a radius of the reciprocal of the incident X-ray wavelength is drawn with the origin of the reciprocal lattice of the crystal at the intersection of the incident beam with the surface of the sphere; diffraction occurs if a reciprocal lattice point intersects the surface of the so-called Ewald sphere; the direction of the diffracted beam is the connection between the center of the Ewald sphere and the intersection point of the relevant reciprocal lattice point.

MAD
Multiple anomalous diffraction, a method to exploit the anomalous scattering effect of a set of natural or artificially introduced anomalous scatterers for the solution of the phase problem.

MIR
Multiple isomorphous replacement, a method to solve the phase problem by preparing isomorphous heavy metal derivatives and measuring X-ray data sets of the native and the derivative crystals.

Phase problem
The phase of the diffracted waves is lost during the measurement as the X-ray intensities deliver the amplitude of the diffracted waves only.

Reciprocal lattice
A lattice in reciprocal space with lattice points, which are perpendicular to the corresponding set of lattice planes in the lattice in direct space with a length of the reciprocal of the lattice plane distance or its multiples.

Resolution
Minimal distance between two objects that can be resolved.

Structure factor
Mathematical expression for the X-ray wave diffracted by a crystal, which consists of amplitude and phase factor.

X-ray diffraction of biomolecules covers diffraction experiments on single crystals of small biological molecules such as oligopeptides, cofactors, steroid hormones, and so on, or biological macromolecules. But it also includes small angle scattering experiments on biological macromolecules in solution. This chapter is exclusively dedicated to the X-ray crystallography of biological macromolecules. It comprises the determination of the three-dimensional structures of proteins, nucleic acids, and other biological macromolecules at atomic resolution by diffraction of X-rays

on crystals of such macromolecules. The atomic structure is obtained from the electron density distribution of the macromolecular crystal, which is the Fourier transform of the waves diffracted by the crystal. The amplitudes of the diffracted waves are determined directly from the diffraction experiment. The diffraction phases are revealed (1) from additional diffraction data of isomorphous heavy atom derivatives (multiple isomorphous replacement (MIR) technique), (2) from multiple anomalous diffraction (MAD), if suitable anomalous scatterers are in the crystal and using tunable synchrotron radiation, and (3) by Patterson search techniques (molecular replacement), if structural information on the biological macromolecule under investigation is available. X-ray crystallography of biological macromolecules is the unique method for the elucidation of the spatial structures at atomic resolution of complex biomolecules with molecular masses greater than 30 kDa. The structures represent a time and spatial average of molecules packed in a crystal. The preparation of suitable crystals may be a limiting factor.

1 Introduction

1.1 Crystals and Symmetry

In a crystal, atoms or molecules are arranged in a three-dimensionally periodic manner by translational symmetry. The crystal is formed by a three-dimensional stack of unit cells, which is called the *crystal lattice* (Fig. 1a and b). The unit cell is built up by three noncollinear vectors **a**, **b**, and **c**. In the general case, these vectors have unequal magnitudes and their mutual angles deviate from 90°. The arrangement of the molecule(s) in the unit cell may be asymmetrical, but very often it is symmetrical. This is illustrated in Fig. 2(a–e) in two-dimensional lattices for rotational symmetries.

In crystals, only 1-, 2-, 3-, 4-, and 6-fold rotations are allowed. This follows from the combination of the lattice properties with rotational operations. Other possible symmetry elements are mirror plane *m*, inversion center, and combination of rotation axis with inversion center (inversion axis). These are the point group symmetries. They can only occur among each other in a few certain combinations of angles. Other angle orientations would violate the lattice properties. The number

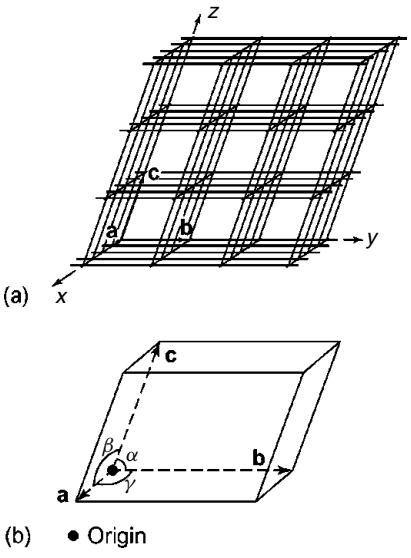

Fig. 1 (a) Crystal lattice and (b) unit cell.

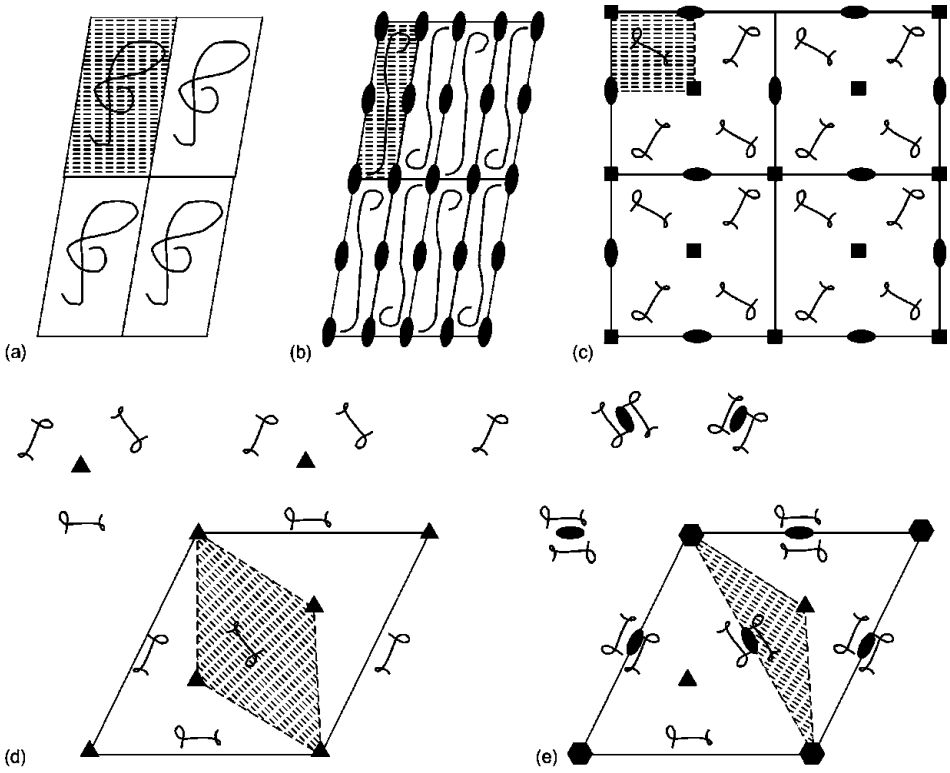

Fig. 2 Rotational symmetry elements in two-dimensional lattices: (a) 1, (b) 2, (c) 4, (d) 3, and (e) 62. The asymmetric unit is hatched.

of all possible combinations reveals the 32 point groups. The crystal morphology obeys the point group symmetries.

Adding an inversion center to the point group symmetry leads to the 11 Laue groups. These are of importance for the symmetry of X-ray diffraction patterns. Their symbols are 1, 2/*m*, 2/*mmm*, 3, 3 *m*, 4/*m*, 4/*mmm*, 6/*m*, 6/*mmm*, *m*3, and *m*3*m*. Proteins and nucleic acids are chiral molecules. Therefore, they can crystallize only in the 11 enantiomorphic point groups: 1, 2, 3, 4, 6, 23, 222, 32, 422, 622, and 432.

The combination of point group symmetries with lattices leads to seven crystal systems, triclinic, monoclinic, orthorhombic, trigonal, tetragonal, hexagonal, and cubic, with 14 different Bravais-lattice types, which can be primitive, face-centered, all-face-centered, and body-centered. Furthermore, additional symmetry elements are generated, having translational components such as screw axes or glide mirror planes. There exist 230 space groups of which 65 are enantiomorphic (for chiral molecules such as proteins). Figure 3 shows the graphical representation for the space group $P2_12_12_1$, as listed in the *International Tables for Crystallography*. The asymmetric unit is one-fourth of the unit cell and can contain one or several molecules. Multimeric molecules may have their own

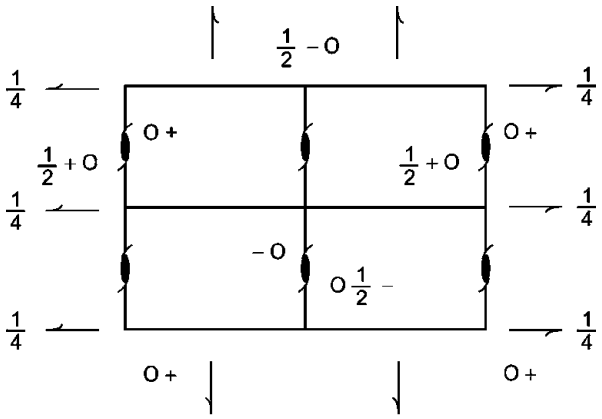

Fig. 3 Graphical representation of space group $P2_12_12_1$.

symmetries, which are called *noncrystallographic symmetries*. Here, axes that are 5-fold, 7-fold, and so on, are also allowed.

1.2 Protein Solubility

Figure 4 shows a typical phase diagram illustrating the solubility properties of a macromolecule. In the labile phase, crystal nucleation and growth compete, whereas in the metastable region, only crystal growth appears. In the unsaturated region, crystals dissolve. The solubility of proteins is influenced by several factors, as follows.

1.2.1 Ionic Strength

A protein can be considered as a polyvalent ion and, therefore, its solubility can be discussed on the basis of the Debye–Hückel theory. In aqueous solution, each ion is surrounded by an "atmosphere" of counter ions. This ionic atmosphere influences the interactions of the ion with water molecules and hence the solubility.

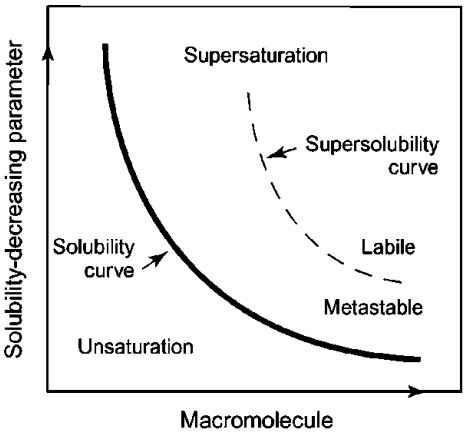

Fig. 4 Phase diagram illustrating the solubility properties of macromolecules. (Reproduced by permission of Academic Press, Inc., from Weber, P.C. (1997) Overview of protein crystallization methods, *Methods Enzymol*. **276**, 13–23.)

1.2.1.1 **"Salting-in"** At low ionic concentration, the "ionic atmosphere" increases the solubility as it increases the possibilities for favorable interactions with water molecules. We obtain (Eq. 1 and 2)

$$\log S - \log S_0 = \frac{AZ_+Z_-\sqrt{\mu}}{1 + aB\sqrt{\mu}} \quad (1)$$

$$\mu = \frac{1}{2}\sum c_j Z_j^2 \quad (2)$$

where μ = ionic strength, S = solubility of the salt at a given ionic strength μ, S_0 = solubility of the salt in absence of the electrolyte, Z_+, Z_- ionic charge of salt ions, A, B = constants depending on the temperature and dielectric constant, a = average diameter of ions, and c_j = concentration of the jth chemical component. Ions with higher charge are more effective for changes in solubility. Most salts and proteins are more soluble in low ionic strength than in pure water. This is termed as *salting-in* (Fig. 5).

1.2.1.2 **"Salting-out"** At higher ionic strength, the ions compete for the surrounding water. Therefore, water molecules are taken away from the dissolved agent and the solubility decreases according to Eq. (3):

$$\log S - \log S_0 = \frac{AZ_+Z_-\sqrt{\mu}}{1 + aB\sqrt{\mu}} - K_s\mu \quad (3)$$

The term $K_s\mu$ predominates at high ionic strengths, which means that "salting-out" is then proportional to the ionic strength (Fig. 5). In a medium with low ionic strength, the solubility of a protein can be decreased by increasing or decreasing the salt concentration. Salts with small, highly charged ions are more effective than those with large, lowly charged ions.

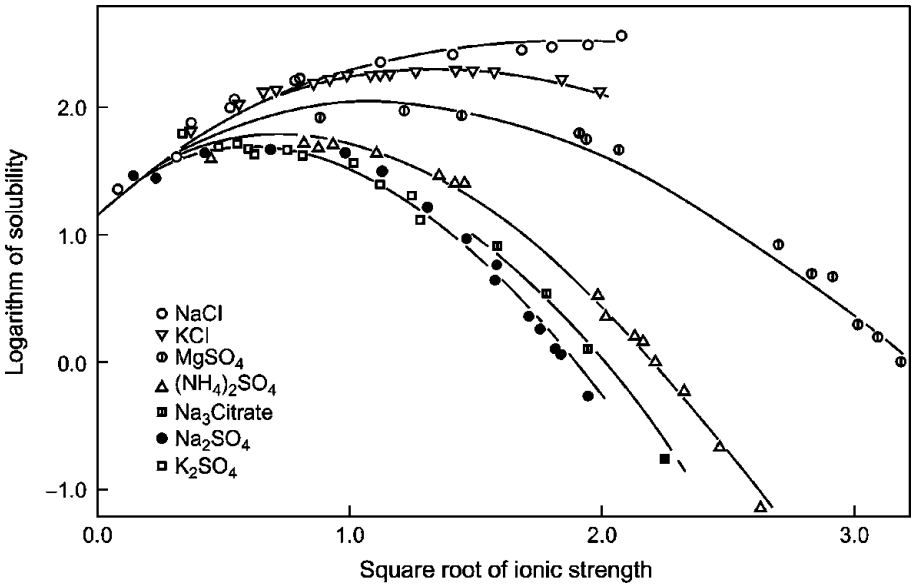

Fig. 5 Solubility of carboxyhemoglobin in various electrolytes at 25 °C. (Reproduced by permission of the American Society for Biochemistry and Molecular Biology, from Green, A.A. (1932) *J. Biol. Chem.* **95**, 47–66.)

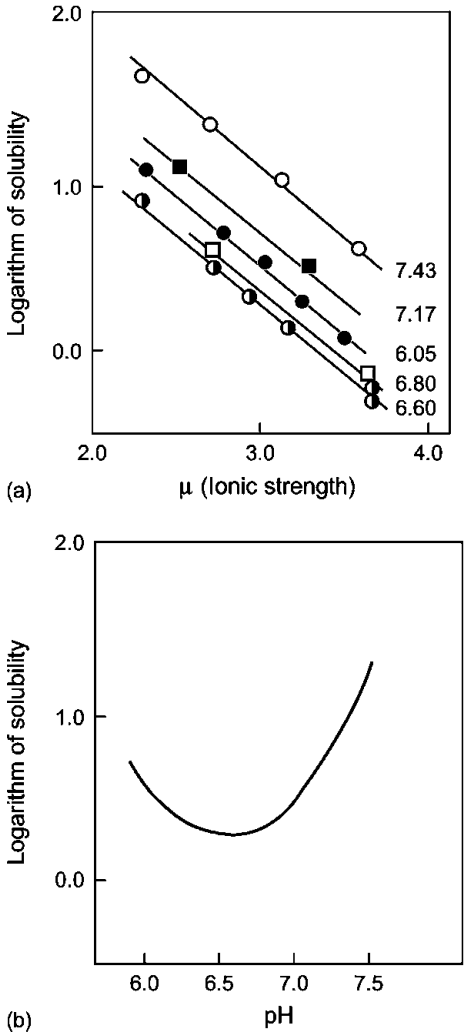

Fig. 6 (a) Solubility of hemoglobin at different pH values in concentrated phosphate buffers; (b) extracted from (a). (Reproduced by permission of the American Society for Biochemistry and Molecular Biology, from Green, A.A. (1931) *J. Biol. Chem.* **93**, 495–516.)

Ammonium sulfate is often used because of its high solubility.

1.2.2 pH and Counterions

A protein is more soluble when its net charge is larger. The minimum solubility is found at the isoelectric point. The net charge is zero and hence the packing in the solid state (in the crystal) is possible owing to electrostatic interactions without the accumulation of a net charge of high energy. All ''salting-out'' curves are parallel, K_s remains constant, and S_0 varies with pH (Fig. 6a and b). In some cases, the isoelectric point is different at low and high ionic strength owing to the interactions of the protein with counterions, which can cause a net charge at the pH of the isoelectric point.

1.2.3 Temperature

Many factors governing protein solubility are temperature dependent. The dielectric constant decreases with increasing temperature. In the solution energy, $\Delta G = \Delta H - T\Delta S$, the entropy term has an increasing influence with increasing temperature. The temperature coefficient of the solubility depends on other conditions (ionic strength, presence of organic solvents, etc.).

At high ionic strength, most proteins are less soluble at 25 °C than at 4 °C, for example the temperature coefficient is negative. The opposite is valid for low ionic strength.

1.2.4 Organic Solvents

The presence of organic solvents leads to a decrease in the dielectric constant. This causes an augmentation of the electric attraction between opposite charges on the surface of the protein molecule and hence to a reduction in solubility. In general, the solubility of a protein is reduced in the presence of an organic solvent if the temperature decreases. Often, organic

solvents denature proteins. Therefore, one should work at low temperatures.

1.3 Experimental Techniques

The whole field of macromolecular crystallography has been excellently reviewed in Volumes 114 and 115 and Volumes 276 and 277 of *Methods in Enzymology*. A collection of review articles concerning the theory and practice of crystallization of biomacromolecules is given in Part A of Carter and Sweet.

A protein preparation to be used in crystallization should be ''pure'' or ''homogeneous'' at a level that established chromatographic methods are providing (protein content $\geq$95%). Furthermore, it should meet the requirements of ''structural homogeneity.'' These requirements can be enumerated as follows. It is first necessary to prepare the protein in an isotypically pure state free from other cellular proteins. It may then be necessary to maintain the homogeneity of the protein preparation against covalent modification during crystallization by adding inhibitors of sulfhydryl group oxidation, by proteolysis, and by the action of reactive metals. It may be necessary to suppress the slow denaturation/aggregation of the protein and to restrict its conformational flexibility to reduce the entropic barrier to crystallization presented by extensive conformational flexibility.

For the crystallization of biomacromolecules, a broad spectrum of crystallization techniques exists. The most common techniques are described here. The oldest and simplest method is batch crystallization (Fig. 7a). In batch experiments, vials containing supersaturated protein solutions are sealed and left undisturbed. In microbatch methods, a small (2–10 μL) droplet containing both protein and precipitant is immersed in an inert oil, which prevents droplet evaporation. In the case that ideal conditions for nucleation and growth are different, it is useful to undertake the separate optimization of these processes. This can be done by seeding, a technique where crystals are transferred from nucleation conditions to those that will support only growth (Fig. 7b). For macroseeding, a single crystal is transferred to an etching solution, then to a solution of optimal growth. In microseeding experiments, a solution containing many small seed crystals, occasionally obtained by grinding a larger crystal, is transferred to a crystal growth solution.

The method of crystallization by vapor diffusion is depicted in Fig. 8(a). In this method, unsaturated precipitant-containing protein solutions are suspended over a reservoir. Vapor equilibration of the droplet and reservoir causes the protein solution to reach a supersaturation level where nucleation and initial crystal growth occur. Changes in soluble protein concentration in the droplet are likely to decrease supersaturation over the time course of the experiment. The vapor diffusion technique can be carried out as hanging drop or sitting drop method.

In crystallization by dialysis, the macromolecular concentration remains constant as in batch methods (Fig. 8b) because the molecules are forced to stay in a fixed volume. The solution composition is changed by diffusion of low-molecular-weight components through a semipermeable membrane. The advantage of dialysis is that the precipitating solution can be easily changed. Dialysis is also uniquely suited to crystallizations at low ionic strength and in the presence of volatile reagents such as alcohols.

1.4
Crystallization Screenings

Screening schemes have been developed that change the most common parameters of this multiparameter problem such as protein concentration, the nature and concentration of the precipitant, pH, and temperature. Each screening can be extended by adding specific additives in low concentrations that affect the crystallization. Sparse matrix crystallization screens are widely applied. The sparse matrix formulation allows one to screen efficiently a broad range of the most popular and effective salts (e.g. ammonium sulfate, sodium and potassium phosphate, sodium citrate, sodium acetate, lithium sulfate), polymers (e.g. poly(ethyleneglycol) (PEG) of different molecular masses (from 400 to 8000)), and organic solvents (e.g. 2,4-methylpentanediol (MPD), 2-propanol, ethanol) versus a wide range of pH. Another approach is the systematic screening of the statistically most successful precipitants. A single precipitant is screened at four unique concentrations versus seven precise levels of pH between 4 and 10. Such grid screens can be done with ammonium sulfate, PEG 6000, MPD, and PEG 6000 in the presence of 1.0 M lithium chloride or sodium chloride. For the crystallization of membrane proteins, for each detergent that is necessary to make the membrane protein soluble, a whole grid screen or sparse matrix screen must be constructed. In principle, all three techniques can be applied for the different screening schemes, but mostly the vapor diffusion technique is applied because it is easy to use and the protein consumption is low. For a typical broad screening, about 2 mg of protein is sufficient. Chryschem plates (sitting drop) or Linbro plates (hanging drops) may be

used for the vapor diffusion crystallization screening experiments. Once crystals have been obtained, their size and quality can be optimized by additional fine screens around the observed crystallization conditions. General rules do not exist that indicate which method for crystallization one has to use for which type of protein. Suggestions for crystallization conditions to be tested can be obtained from the Biological Macromolecule Crystallization Database.

2 Experimental Techniques

2.1 X-ray Sources

2.1.1 Conventional X-ray Generators

X-rays are produced when a beam of high-energy electrons, which have been accelerated through a voltage V in a vacuum, hit a target. An X-ray tube run at voltage V will emit a continuous X-ray spectrum with a minimum wavelength given by Eq. (4):

$$\lambda_{\min} = \frac{hc}{eV} = \frac{12398}{V} \qquad (4)$$

with λ in angströms ($1\ \text{Å} = 10^{-10}$ m) and V in volts. The critical voltage, V_0, which is required to excite the characteristic line of a particular element, can be calculated from the corresponding wavelength for the appropriate absorption edge. For the copper absorption edge, $\lambda_{ae} = 1.380$ Å. Hence, we have (Eq. 5)

$$V_0 = \frac{12398}{\lambda_{ae}} = 8.98\ \text{kV} \qquad (5)$$

Provided that $V > V_0$, the characteristic line spectra will be produced (Fig. 9). The oldest and cheapest X-ray sources are sealed X-ray tubes. The cathode and anode are situated under vacuum in a sealed glass tube, and the heat generated at the anode is removed by a water-cooling system. For the generation of higher intensities, as needed in protein crystallography, one has to use a rotating anode (Fig. 10). Here the anode is rotated, which allows a higher power loading at the focal spot. In protein crystallography, copper targets are usually taken. The used take-off angle is near 4°, which results in apparent focal spot sizes of about 0.3×0.3 mm.

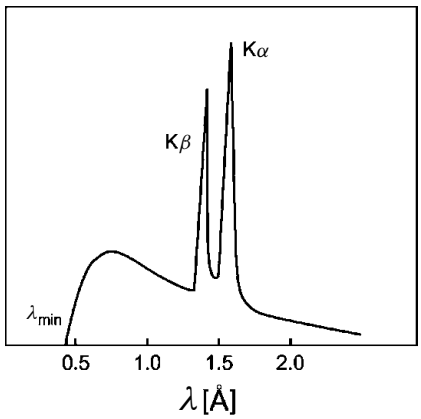

Fig. 9 X-ray spectrum emitted from a copper anode. It shows the continuous "Bremsspektrum" starting at λ_{min} and the two characteristic copper lines λ K$\alpha = 1.5418$Å (superposition of λ K$\alpha_1 = 1.5405$ Å and λ K$\alpha_2 = 1.5443$ Å) and λ K$\beta = 1.3922$ Å.

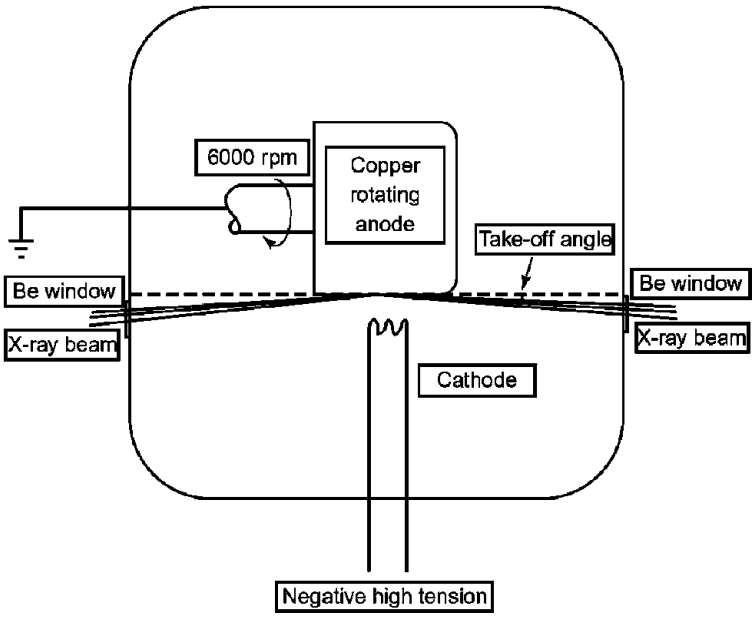

Fig. 10 Schematic drawing of a rotating anode tube. Take-off angle is near 4°. For copper, the tube is normally operated at 50-kV high tension and 100-mA cathode current.

2.1.2 Synchrotron Radiation

As electrically charged particles such as electrons or positrons of high energy are kept under the influence of magnetic fields and travel in a pseudocircular trajectory, synchrotron radiation is emitted and can be used in many different types of experiments. The particles are injected into the storage ring directly from a linear accelerator or through a booster ring. They circulate in a high vacuum for several hours at a relative constant energy. To keep the bunched particles traveling in a nearly circular path, a lattice of bending magnets is set up around the storage ring. As the particle beam traverses each magnet, the path of the beam is altered, and synchrotron radiation is emitted. The loss of energy of the particle beam is compensated by a radiofrequency input at each cycle. The synchrotron radiation can be channeled through different beamlines for use in research.

Other types of magnets – insertion devices called *wigglers* and *undulators* – can be assembled in the storage ring. Unlike the bending magnets, the primary purpose of which is to maintain the circular trajectory, wigglers and undulators are used to increase the intensity of the emitted radiation. Bending magnets and wigglers cause a continuous spectrum of radiation.

In contrast, the radiation produced by an undulator has a discontinuous spectrum, and can be tuned to various wavelengths. The importance of synchrotron radiation for macromolecular crystallography lies in the high brilliance (photons s^{-1} $mrad^{-2}$ mm^{-2} per $\Delta\lambda/\lambda$; that is, how small is the source and how well collimated are the X-rays?) of the beam, the

high intensity, and the tunability of the wavelength in the relevant range from 0.5 to 3.0 Å. The time structure of the beam is of interest for time-resolved crystallography. The particles circulate in bunches with widths of 50 to 150 ps and repeat every few microseconds.

About 15 synchrotron radiation facilities equipped with beamlines for macromolecular crystallography are available throughout the world operated at energies from about 1.5 to 6 to 8 GeV for third-generation machines. An aerial view of the European Synchrotron Radiation Facility (ESRF) in Grenoble, a third-generation machine, is shown in Fig. 11. The ESRF storage ring is operated at 6 GeV and has a circumference of 844.39 m. Its critical wavelength, λ_c, is 0.6 Å.

2.1.3 Monochromators

In the majority of applied diffraction techniques, monochromatic X-rays are used. Therefore, the emitted white radiation of X-rays must be further monochromatized. With copper Kα radiation generated by a sealed or rotating anode tube, the Kβ radiation can be removed with a nickel filter. Much better results can be achieved with a monochromator. The simplest monochromator is a piece of a graphite crystal that reflects the copper Kα radiation at a Bragg angle of 13.1° and a glancing angle of 26.2°. Improved beam focusing is obtained by a double mirror system. The mirror assembly is composed of two perpendicular bent nickel-coated glass optical flats, each with translation, rotation, and slit components housed in a helium gas-flashed chamber, which is commercially available (Molecular Structure Corporation, The Woodlands, TX, USA). The prototype and basic theory in the use of this system were discussed in detail by Phillips and Rayment.

For synchrotron radiation with its much higher intensity, germanium or silicon single crystals can be applied as monochromators, which filter out a bandwidth of $\delta\lambda/\lambda$ from 10^{-4} to 10^{-5}, two orders of magnitude smaller than that with graphite. Single or double monochromators can be used, which are either flat or bent. The bent monochromators have the advantage that

Fig. 11 Aerial view of ESRF in Grenoble. Courtesy of ESRF.

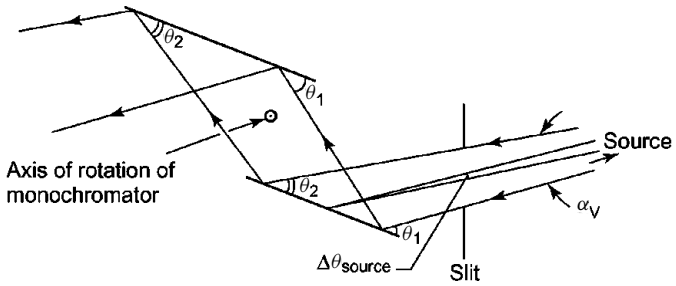

Fig. 12 Schematic drawing of a double monochromator system. (Reproduced by permission of Cambridge University Press, from Helliwell, J.R. (1992) *Macromolecular Crystallography with Synchrotron Radiation*, Cambridge University Press, Cambridge.)

they simultaneously focus the beam. The double monochromator (Fig. 12) has the advantage that the emergent monochromatic beam is parallel to and only slightly displaced from the incident synchrotron radiation beam. This makes necessary only small adjustments of the X-ray optics and detector arrangement when it is tuned to another wavelength compared to a single monochromator where the whole X-ray diffraction assembly must be moved.

2.2 Detectors

2.2.1 General Components of an X-ray Diffraction Experiment

A principal arrangement for a macromolecular X-ray diffraction experiment is depicted in Fig. 13. The primary beam leaves the X-ray source and passes the X-ray optics, which may be a simple collimator or the various types of monochromators or mirror systems described above,

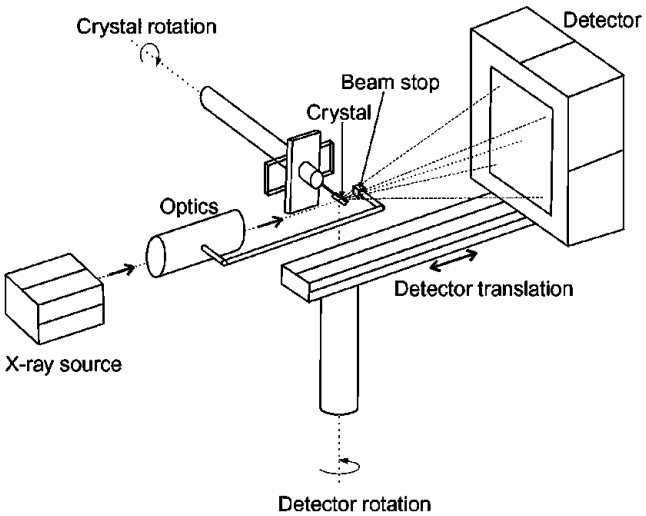

Fig. 13 Principal arrangement for a macromolecular X-ray diffraction experiment.

and terminated with a collimator. The crystal is mounted on a goniometer head either in a quartz capillary or in a cryo-loop shock-frozen at low temperature. The goniometer head is attached to a device that can perform spatial movements of the crystal around the center of the crystal. The simplest kind of such a movement is the rotation of the crystal about a spindle axis as indicated in Fig. 13. This device can be a multiple axis goniostat (2–4 axes), which allows the crystal to be brought into any spatial orientation around its center. The X-ray detector, which registers the diffracted intensities, is mounted on a device that permits the translation and rotation of the detector. If the active area of the detector is large enough to collect all generated diffracted beams at a given wavelength, detector rotation is not necessary and the detector is arranged normal to the primary beam. A small piece of lead is placed in the path of the primary beam just behind the crystal to prevent damage to the detector and superfluous gas scattering.

The classical detectors in macromolecular crystallography have been photographic films and single-photon counters. The photographic films were used on specially designed X-ray cameras and the single-photon counters on four-circle diffractometers. The main disadvantage of these detectors was their low sensitivity and with films the limited dynamic range (1 : 200). Over the last 15 years, powerful detectors have been developed, which will be discussed briefly. These new detectors have almost completely replaced photographic films and single-photon counters.

2.2.2 Image Plates

An image plate (IP) consists of a support (either a flexible plastic plate or a metal base) coated with a photostimulable phosphor (150 μm) and a protective layer (10 μm). The photostimulable phosphor is a mixture of very thin crystals of $BaF(Br,I):Eu^{2+}$ and an organic binder. This phosphor can store a fraction of the absorbed X-ray energy by electrons trapped in color centers. It emits photostimulated luminescence, whose intensity is proportional to the absorbed X-ray intensity, when later stimulated by visible light. The wavelength of the photostimulated luminescence ($\lambda \approx 390$ nm) is reasonably separated from that of the stimulating light ($\lambda \approx 633$ nm, in practice a red laser), allowing it to be collected by a conventional high quantum efficiency photomultiplier tube. The output of the photomultiplier is amplified and converted to a digital image, which can be processed by a computer. The residual image on the IP can be erased completely by irradiation with visible light, to allow repeated use.

IPs have several excellent performance characteristics as integrating X-ray area detectors that make them well suited in X-ray diffraction. The sensitivity is at least 10 times higher than for X-ray films and the dynamic range is much broader ($1:10^4$–10^5). Important for synchrotron radiation is their high sensitivity at shorter wavelengths (e.g. 0.65 Å). A disadvantage is the relatively long readout times for each exposure (from 45 s to several min). IP diffractometer systems are commercially available from several companies. All systems work reliably and deliver good-quality data. A photograph of the newest IP system produced by Mar Research (Norderstedt, Germany) is shown in Fig. 14.

2.2.3 Gas Proportional Detectors

As X-ray counters, gas proportional detectors provide unrivaled dynamic range and sensitivity for photons in the range important for macromolecular crystallography.

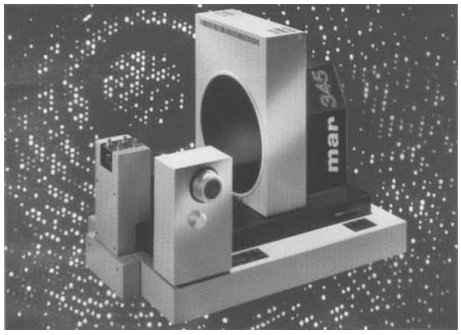

Fig. 14 Mar 345 IP diffractometer system from Mar Research, Norderstedt, Germany. The circular plate rotates for scanning and the laser is moved along a radial line. Courtesy of Mar Research.

The classical gas proportional detector is a multiwire proportional chamber (MWPC), widely used as an in-house detector with conventional X-ray sources. Two MWPC diffractometer systems are commercially available. Gas proportional detectors use as a first step the absorption of an X-ray photon in a gas mixture high in xenon or argon. This photoabsorption produces one electron–ion pair whose total energy is just the energy of the initial X-ray photon. The ion returns to its neutral state either by emission of Auger electrons or by fluorescence. Since the kinetic energy of these first electrons is far greater than the energy of the first ionization level of the xenon or argon atoms, fast collisions with atoms (or molecules) in the gas very quickly produce a cascade of new electron–ion pairs in a small region extending over a few hundred micrometers around the conversion point. The total number of primary electrons that are produced during this process is proportional to the energy of the absorbed X-ray photon and is thus a few hundred for ~10-keV photons. These primary electrons then drift to the nearest anode wire where an ionization avalanche of as many as 10 000 to 1 000 000 ion pairs results. The motion of the charged particles in this avalanche (chiefly the motion of the heavy positive ions away from the anode wire) causes a negative-going pulse on the anode wire and positive-going pulses on a few

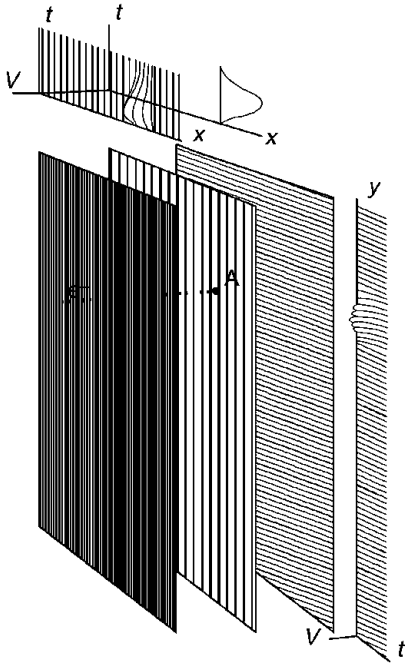

Fig. 15 Expanded view of an MWPC, showing the anode plane sandwiched between the two cathode planes. A is the position of the avalanche. The centers of the induced charge distributions are used to determine the coordinates, *x* and *y*, of the avalanche. (Reproduced by permission of Academic Press, Inc., from Kahn, R., Fourme, R. (1997) *Methods Enzymol.* **276**, 244–268.)

of the nearest wires in the back (cathode) wire plane (see Fig. 15).

Disadvantages of the MWPC detector are the limited counting rate due to the buildup of charges in the chamber and limitations in the readout electronics and the lower sensitivity at shorter wavelengths. This makes the application of MWPCs with synchrotron radiation poorly effective.

2.2.4 Charge-coupled Device-based Detectors

A remarkable development for the use with synchrotron radiation is the design and construction of charge-coupled device (CCD) detectors. CCDs were developed originally as memory devices, but the observation of localized light-induced charge accumulation in CCDs quickly led to their development as imaging sensors. These CCD detectors are integrating detectors like the conventional X-ray sensitive film, IPs, and analog electronic detectors using either silicon intensified target (SIT) or CCD sensors. Integrating detectors have virtually no upper rate limits because they measure the total energy deposited during the integration period (although individual pixels may become saturated if the signal exceeds its storage capacity).

The first commercially available analog electronic detector was the fast area television detector (FAST) detector produced by Enraf-Nonius (Delft, The Netherlands). This detector contained a SIT vidicon camera as an electronically readable sensor. The SIT vidicon exhibits higher noise than CCDs, which have therefore replaced SIT sensors during the past few years. Because of their high intrinsic noise, detectors with SIT vidicon sensors need an analog image-amplification stage and this limits the overall performance of such detectors. Several CCD detector systems have also been developed that incorporate image intensification. The most important development in detector design for macromolecular crystallography has been the incorporation of scientific-grade CCD sensors into instruments with no image intensifier. These detector designs are based on direct contact between the CCD and a fiber-optic taper. There are several commercial systems available based on this construction (Mar Research, Norderstedt, Germany; Hamlin Detector).

A schematic representation of such a detector is shown in Fig. 16. An X-ray phosphor (commonly $Gd_2O_2S:Tb$) is attached to a fiber-optic faceplate, which is tightly connected to a fiber-optic taper. The X-ray sensitive phosphor surfaces at the front convert the incident X-rays into a burst of visible-light photons. Although it is possible to permit the X-rays to strike the CCD directly, this method has several drawbacks, such as radiation damage to the CCD, signal saturation, and poor efficiency. The use of a larger phosphor as active detector area and the demagnifying fiber-optic taper is also necessary because the size of the scientific-grade CCD sensors is not as large as needed for the demands of the X-ray diffraction experiment. The fiber-optic taper is then bonded to the CCD, which is connected to the electronic readout system. The CCD must be cooled to temperatures ranging from -40 to $-90\,^{\circ}C$, depending on the various systems. The great advantage of CCD detectors is their short readout time, which lies in the range from 1 to a few seconds.

2.3 Crystal Mounting and Cooling

2.3.1 Conventional Crystal Mounting

The purpose of crystal mounting is to isolate a single crystal from its growth

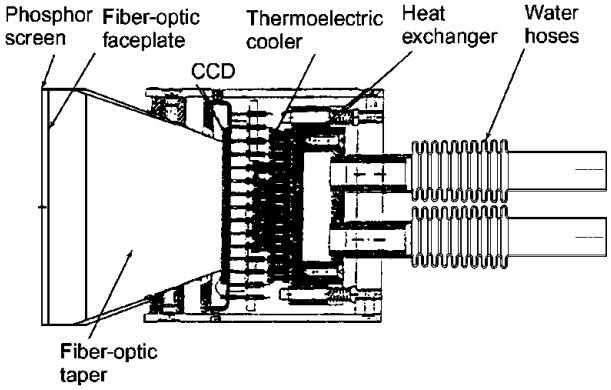

Fig. 16 Schematic representation of a CCD/taper detector. (Reproduced by permission of Academic Press, Inc., from Westbrook, E.M., Naday, I. (1997) *Methods Enzymol.* **276**, 268–288.)

medium so that it can be used in the X-ray diffraction experiment to study its diffraction properties. It is important that the manipulation of the crystal introduces as little damage as possible to its three-dimensional structure. The most important aspect of crystal mounting is to preserve the crystal in its state of hydration. This is accomplished by sealing the crystal in a thin-walled (0.001-mm thick) glass or quartz capillary tube. The important steps in conventional crystal mounting are illustrated in Fig. 17(a–c). The crystal must be dislodged from the surface on which it grew, and then it may be drawn into the capillary using suction from a small-volume (0.25 mL) syringe, micropipet, or mouth aspirator, which are connected to the funnel of the capillary by a flexible plastic hose of appropriate diameter. Next, the capillary should be inverted to allow the crystal to fall to the inner meniscus. Then, the surrounding solution may be removed using thin strips of filter paper or by a small glass pipet. The extent to which the crystal should be dried must be determined by experience. The final step is to place a small volume of mother liquor in the capillary and seal both ends. The capillary is then glued to a metal base, which can be attached to a goniometer head.

2.3.2 **Cryocrystallography**

Many macromolecular crystals suffer from radiation damage when exposed to X-rays with energies and intensities as used in macromolecular X-ray diffraction experiments with both conventional sources and synchrotron radiation. A possibility for reducing radiation damage of the crystal during the measurement is to cool the crystal to low temperatures, usually to 100 K. For this purpose, the crystal is flash-frozen to prevent ice formation or damage to the crystal. One method of crystal treatment is the removal of external solution by transferring the crystal in a small drop to a hydrocarbon oil and either teasing the liquid away or drawing it off with filter paper or a small pipet. The oil-coated crystal is then mounted on a glass fiber or small glass "spatula." Oil protects the crystal from drying and acts as an adhesive that hardens on cooling to hold the sample rigidly. Much more frequently used

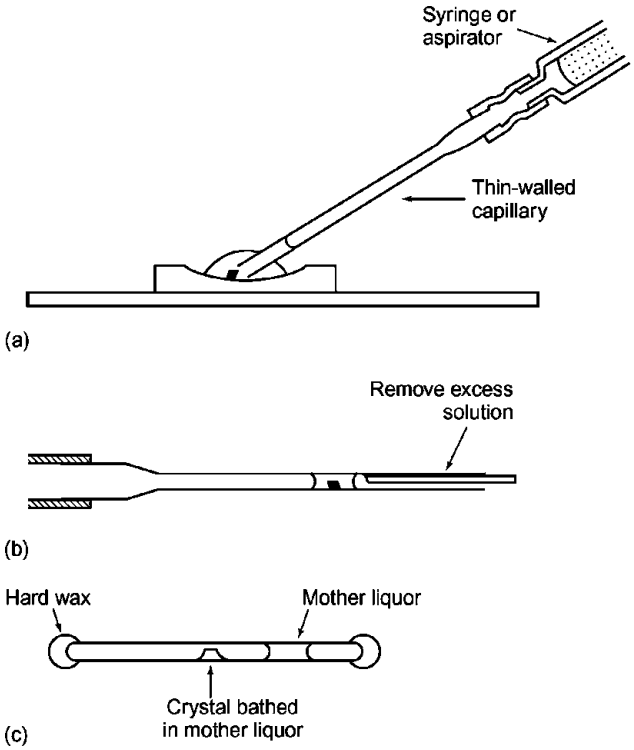

Fig. 17 Mounting of a crystal in a glass capillary. (Reproduced by permission of Academic Press, Inc., from Rayment, I. (1985) *Methods Enzymol.* **114**, 136–140.)

is a technique in which the crystal is suspended in a film of mother liquor in a small loop. This method avoids problems with damage by the oil or mechanical damage when removing the external liquid, and it has proven successful for most samples. It does, however, require the use of a cryoprotectant to prevent ice formation. The most commonly used cryoprotectants are glycerol, PEG of different molecular weights, glucose, and MPD.

The loop is produced from fine fibers that permit unobstructed data collection in nearly all sample orientations. The crystal is held within the loop, suspended in a thin film of cryoprotectant-containing harvest buffer. The loop is supported by a fine wire or pin, which itself is attached to a steel base used for placing the assembly on a goniometer head and in storing mounted crystals. Once in the loop, the crystal is cooled to a temperature at which the increasing viscosity of the liquid prevents molecular rearrangement. The rate of cooling must be rapid enough to reach this point before ice-crystal nucleation occurs. Two methods are used: cooling directly in the gas stream of a cryostat or plunging the crystal into a cryogenic liquid. The first method is explained in Fig. 18(a) and (b). The loop assembly (with crystal) is attached to the goniometer head, with the cold stream deflected. Then, the cold stream is unblocked to flash-freeze

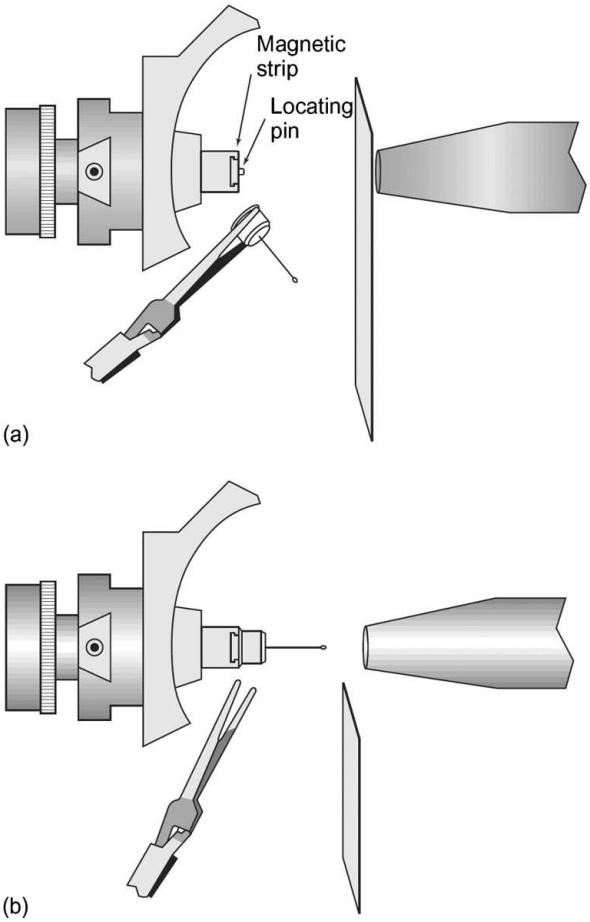

Fig. 18 Flash cooling in the direct cold gas stream of a cryostat. (Reproduced by permission of Academic Press, Inc., from Rodgers, D.W. (1997) *Methods Enzymol.* **276**, 244–268.)

the crystal. In this gas-stream position, the goniometer head must be heated to prevent ice formation on the goniometer head. Cryostats and cryocrystallographic tools are commercially available.

Cryocrystallography has had a great impact on macromolecular crystallography by dramatically increasing the lifetime of a crystal during the X-ray experiment allowing, for example, the collection of several data sets from one crystal at different wavelengths using synchrotron radiation.

2.3.3 Crystal Quality Improvement by Humidity Control

The crystal quality is of decisive significance for a successful X-ray crystal structure determination. Two principal cases must be distinguished: (1) the crystals diffract to a resolution only (>4.5 Å), which does not allow a structure determination at all and (2) the crystal quality is good enough to elucidate its 3-D structure (resolution <3.5 Å but not better than 2.5 Å) but a structure determination at

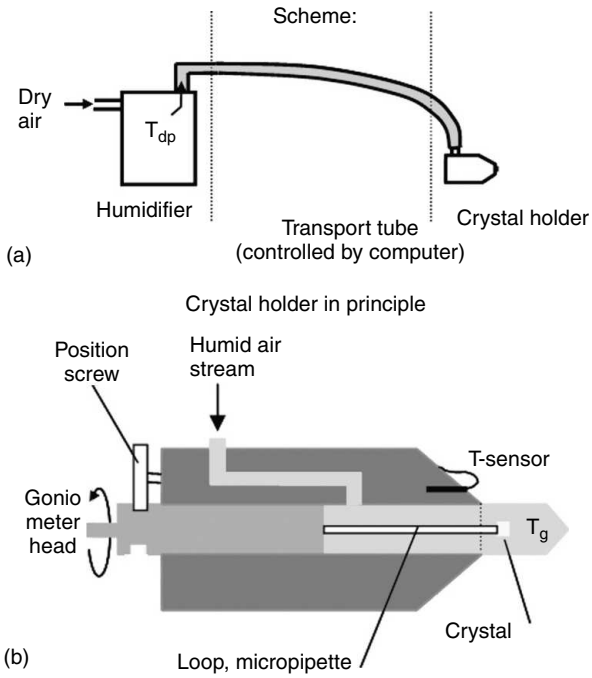
higher resolution and accuracy therewith would be necessary, for example, for the characterization of a metal center in a metalloprotein. The control of the crystal packing via the solvent content of a crystal is a useful approach for the improvement of the crystal quality of biological macromolecules. For this purpose, a so-called Free Mounting System (FMS) has been developed and successfully applied. The principal construction of the FMS is shown in Fig. 19 (a). A main part of the FMS is the humidifier unit, which consists of the humidifier, the control, and power electronics. A stream of humid air with defined moisture is produced. A flexible teflon tube transports the humid air to the crystal holder, which is depicted in Fig. 19 (b). A very compact construction allows the sample to be mounted in a controlled environment with minimal restriction for the X-ray measurement. The head part is freely rotatable relative to the insert, without axial movement. A heating element and a temperature sensor are integrated into the head part. The humid air stream through the head part is adjusted to the temperature of the head part, independent of the ambient temperature. The crystal may either be mounted in a patch-clamp pipette or conventional cryo-loop (Fig 19 (c)).

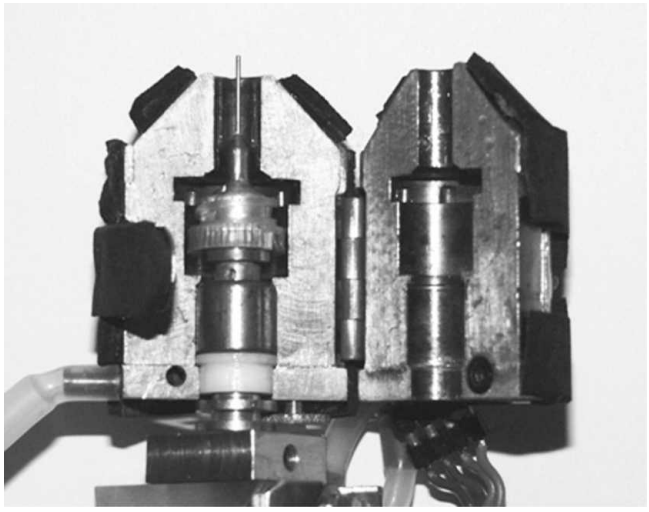
In a typical experiment to increase the crystal quality, X-ray crystal diffraction is monitored at various defined crystal humidities. Usually, a positive effect is observed at lower humidity, which causes shrinkage of the unit cell volume and allows different and possibly more favorable crystal contacts. After having found the optimal condition, the crystal, mounted in a loop, can be shock-frozen for a subsequent data collection. A remarkable improvement of crystal quality by using the FMS could be observed with about 30% of different projects under investigation.

2.4 Data-collection Techniques

2.4.1 Rotation Method

Most macromolecular X-ray diffraction systems use the rotation method for data collection. For each crystal, a reciprocal lattice can be constructed, which is very useful in the interpretation of crystallographic crystal diffraction experiments. Diffraction theory (discussed later) tells us that an X-ray reflection is generated when a point of this reciprocal lattice lies on a sphere of radius $1/\lambda$ whose origin is $1/\lambda$ away from the origin of the reciprocal lattice in the direction of the primary beam (Fig. 20). The direction of such a diffracted beam is along the connection of the center of the so-called Ewald sphere (radius $1/\lambda$) and the intersection of the reciprocal lattice point on the Ewald sphere. Owing to certain factors, which will be discussed later, the apparent reciprocal lattice extends to a given radius only, which defines the resolution sphere. To bring all the reciprocal lattice points within the resolution sphere into the reflection position, the crystal must be rotated around its center. Nearly all macromolecular X-ray diffraction systems apply the rotation technique in the normal beam case where the rotation axis is normal to the incident X-ray beam. Rotating the crystal around 360° brings all reciprocal lattice points within the resolution sphere in the reflection position except for the region between the rotation axis and the Ewald sphere, which is therefore called the *blind region*. This region can be collected when the crystal has been brought into another orientation. The diffracted beams are usually registered with a flat detector at distance D from the crystal, which is also normal to the primary beam. To avoid overlapping of reflection





(c)

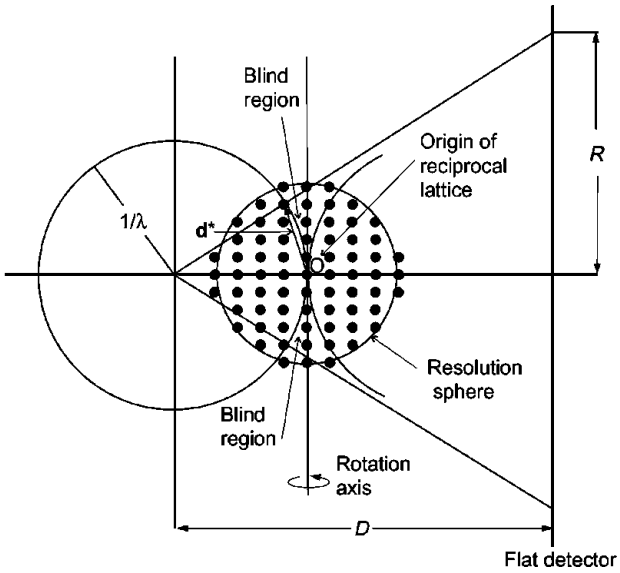

Fig. 20 Diffraction geometry in the rotation method usually applied in macromolecular X-ray diffraction systems.

spots on the detector, the crystal is rotated by rotation-angle increments, which can vary from tenths of degrees to 1 or to a few degrees, depending on the size of the crystal unit cell, crystal mosaicity, beam collimation, and other factors. Each individual exposure is processed and electronically stored in a computer. These raw data images are evaluated subsequently with relevant computer programs (discussed in some detail later) to give the intensities and geometric reference values (indices) for each collected intensity.

2.4.2 **Precession Method**

The rotation method delivers a distorted image of the reciprocal lattice for each geometry of the detector (flat or curved) and orientation with respect to the rotation axis. An undistorted image of the reciprocal lattice can be obtained by using the precession method. The principle of this technique is shown in Fig. 21. The detector is a flat film. During the motion of a given reciprocal lattice plane (in Fig. 21, a so-called zeroth plane going through the origin O of the reciprocal lattice), the flat detector must always be parallel to this reciprocal lattice plane to obtain an undistorted image of this plane. The normal of the reciprocal lattice plane and, consequently, also the detector are inclined with respect to the primary X-ray beam by an angle μ. When the normals of the reciprocal lattice plane and the detector carry out a concerted precession motion of angle μ around the primary X-ray beam, a circular region of the reciprocal lattice plane is registered on the detector (these regions are shown as dashed circles in Fig. 21). In a precession camera construction, the crystal and the film cassette are both held in a universal joint, which are linked so that the film and crystal move together in phase with precession angle μ. In Fig. 21, the joints are symbolized as forks and their linkage by a line. Parallel to

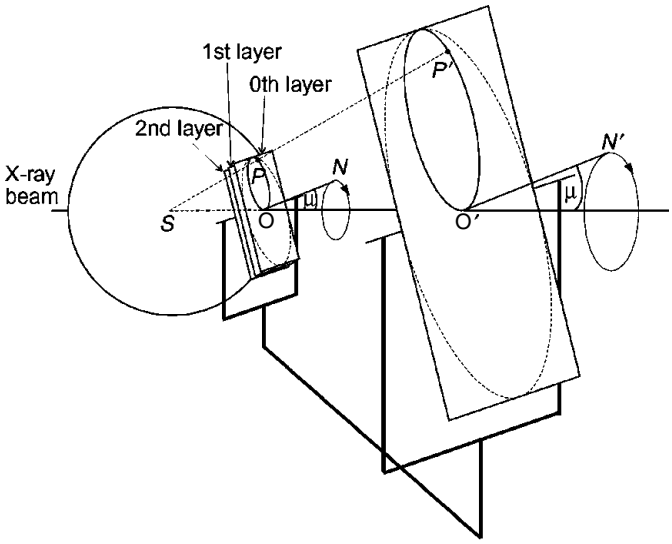

Fig. 21 Principle of the precession method (modified from Buerger, M.J. (1964) *The Precession Method in X-ray Crystallography*, John Wiley & Sons, New York).

the zeroth reciprocal lattice plane is a set of lattice planes that also carry out this precession movement. The parts of them that are swung through the Ewald sphere also give rise to an image on the flat detector (first and second reciprocal lattice layers are also indicated in Fig. 21). The images of these layers would superimpose on the detector, and the use of the technique in this way is denoted by the screenless precession method. The insertion of a screen with a suitable annular aperture between the crystal and the detector at an appropriate distance can be used to screen out the desired reciprocal layer. This screen is also inclined by the precession angle μ and is coupled to the concerted precession movement of crystal and film cassette. The strength of the precession technique is that in addition to the undistorted imaging of the reciprocal lattice planes, the indexing of the diffraction spots is straightforward and the symmetry of the diffraction pattern is readily obtained by inspection.

For this reason, the precession method has been broadly applied in macromolecular crystallography for a long time. The replacement of film by the new generation of detectors has almost completely stopped the use of the precession method. Nevertheless, the use of a precession camera has great teaching benefits in becoming familiar with the reciprocal lattice concept.

3
Principles of X-ray Diffraction by a Crystal

3.1
Scattering of X-rays by an Atom

A component of the electrical field of the incident wave has the following form (Eq. 6) in free space referred to an origin at $\mathbf{x} = 0$:

$$E(\mathbf{x}) = E_0 \exp[2\pi i(\nu t - \mathbf{x}\mathbf{s}_0)] \qquad (6)$$

where $\mathbf{s}_0$ = wave vector of incident wave, $\nu = c/\lambda$ = frequency, λ = wavelength, and $s_0 = 1/\lambda$ = absolute value of incident wave vector. This wave interacts with a scattering center at position $\mathbf{r}$ (Fig. 22). The electric field component of the incident wave causes the electron at position $\mathbf{r}$ to oscillate. Together with the positively charged nucleus of the atom, which does not oscillate, this can be considered as a classical dipole oscillator. This dipole oscillator emits a spherical wave, which is denoted as a scattered wave and can be given in the following form (Eq. 7 and 8):

$$E_{SC} = CE(\mathbf{r})\frac{\exp(-2\pi i s_0 r_1)}{r_1} \quad (7)$$

$$E_{SC} = CE_0 \exp(-2\pi i \mathbf{s}_0 \mathbf{r}) \times \frac{\exp(2\pi i(\nu t - s_0 r_1)}{r_1} \quad (8)$$

The phase-angle-dependent factor has been omitted. The amplitude of the scattered wave is proportional to the amplitude $E(\mathbf{x})$ of the wave incident at $\mathbf{r}$. This gives the factor $E(\mathbf{r})$. C is a proportionality factor, taking into account the peculiarities of the scattering center. The factor $1/r_1$ considers the conservation of the scattered energy flux. We add all wavelets scattered from different volume elements of an atom to get the total amplitude of the scattered wave at point $\mathbf{R}$ relative to the origin O in the atom.

Equations 9 to 12 follow from Fig. 22:

$$\mathbf{r} + \mathbf{r}_1 = \mathbf{R} \quad (9)$$

$$r_1^2 = (\mathbf{R} - \mathbf{r})^2 = R^2 + r^2 - 2rR\cos(\mathbf{r}, \mathbf{R}) \quad (10)$$

$$r_1 = R\left[1 - \frac{2r}{R}\cos(\mathbf{r}, \mathbf{R}) + \left(\frac{r}{R}\right)^2\right]^{1/2} \quad (11)$$

$$r_1 \approx R\left(1 - \frac{r}{R}\cos(\mathbf{r}, \mathbf{R}) + \dots\right) \quad (12)$$

where $(r/R)^2$ and higher terms were neglected in the expansion of the square root. It follows that (Eq. 13)

$$r_1 \approx R - r\cos(\mathbf{r}, \mathbf{R}) \quad (13)$$

Now we can combine the spatial phase factors in the equation for E_{SC}. With the approximation for r_1, we obtain Eq. (14):

$$\exp(-2\pi i(\mathbf{s}_0\mathbf{r} + s_0 r_1) = \exp(-2\pi i s_0 \mathrm{R}) \times \exp(-2\pi i(\mathbf{s}_0\mathbf{r} - s_0 r\cos(\mathbf{r}, \mathbf{R})) \quad (14)$$

As $s_0 = s$ and $\mathbf{s}$ is parallel to $\mathbf{R}$, we obtain Eq. (15).

$$s_0 r\cos(\mathbf{r}, \mathbf{R}) = sr\cos(\mathbf{r}, \mathbf{s}) = \mathbf{sr} \quad (15)$$

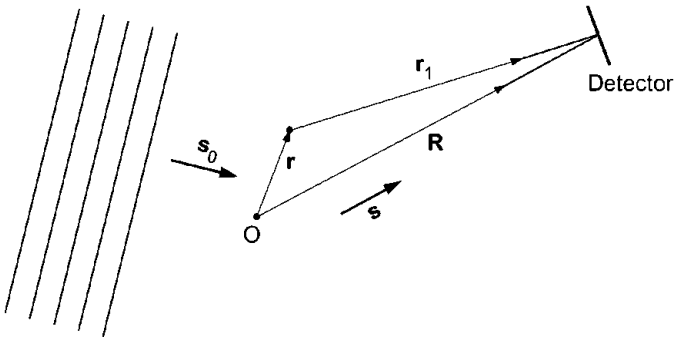

Fig. 22 Scattering of a planar X-ray wave by an electron at position $\mathbf{r}$ with respect to origin O.

It follows for the phase factor (Eq. 16):

$$\exp(-2\pi i(\mathbf{s}_0\mathbf{r} + s_0 r_1) = \exp(-2\pi i s_0 \mathrm{R}) \times \exp(-2\pi i(\mathbf{s}_0\mathbf{r} - \mathbf{sr})) = \exp(-2\pi i \mathbf{S}_0 \mathrm{R}) \times \exp(2\pi i(\vec{\mathbf{r}}(\vec{\mathbf{S}} - \vec{\mathbf{S}}_0)) \quad (16)$$

Now we can write for the wave scattered by a center at $\mathbf{r}$ (Eq. 17):

$$E_{\mathrm{SC}} = \left(\frac{CE_0 \exp(-2\pi i s_0 R) \exp(2\pi i \nu t)}{R}\right) \times \exp(2\pi i \mathbf{r}(\mathbf{s} - \mathbf{s}_0)) \quad (17)$$

In a useful approximation, r_1 has been replaced by R in the denominator. In general, the scattering from an atom comes from the distribution of electrons in the atom. If the scattering of a volume element $\mathrm{d}v$ of the atom is proportional to the local electron density ρ $(\mathbf{r})$, then the scattering amplitude will be proportional to the integral (Eq. 18):

$$f(\mathbf{S}) = \int_{\text{vol. of atom}} \rho(\mathbf{r}) \exp(2\pi i \mathbf{r}\mathbf{S}) \mathrm{d}v \quad (18)$$

3.2 Scattering of X-rays by a Unit Cell

A unit cell may contain N atoms at positions of their internal origins at $\mathbf{r}_j$ $(j = 1, 2, 3, \ldots, N)$ with respect to the origin of the unit cell (Fig. 23). For atom 1, we obtain Eq. (19):

$$\mathbf{f}_1 = \int_{\text{vol. of atom}} \rho(\mathbf{r}) \exp[2\pi i(\mathbf{r}_1 + \mathbf{r})\mathbf{S}] \mathrm{d}v = f_1 \exp(2\pi i \mathbf{r}\mathbf{S}) \quad (19)$$

with (Eq. 20)

$$f_1 = \int_{\text{vol. of atom}} \rho(\mathbf{r}) \exp 2\pi i \mathbf{r}_1 \mathbf{S} \mathrm{d}v \quad (20)$$

where f_1 is the atomic form factor for atom 1. It reflects the characteristics of the scattering of the individual atoms and is real if the wavelength of the incident X-ray is not close to an absorption edge of the atom. The atomic form factor f is equal to Z, the ordinary number of the scattering atom, at a diffraction angle of 0° and decreases with increasing diffraction angle. For N atoms, this adds up to the total scattered wave of a unit cell $\mathbf{G}(\mathbf{S})$ (Fig. 24) according to Eq. (21):

$$\mathbf{G}(\mathbf{S}) = \sum_{j=1}^{N} f_j \exp(2\pi i \mathbf{r}_j \mathbf{S}) \quad (21)$$

3.3 Scattering of X-rays by a Crystal

3.3.1 One-dimensional Crystal

In a one-dimensional crystal, the unit cells are separated by the unit cell vector $\mathbf{a}$. The contribution of the scattered wave

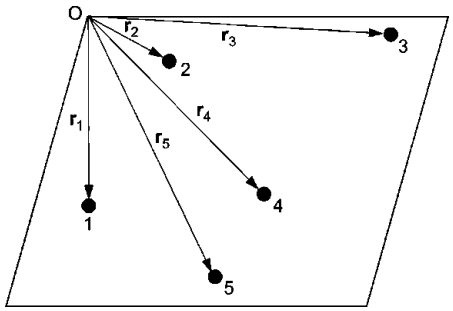

Fig. 23 Atomic positions in a unit cell.

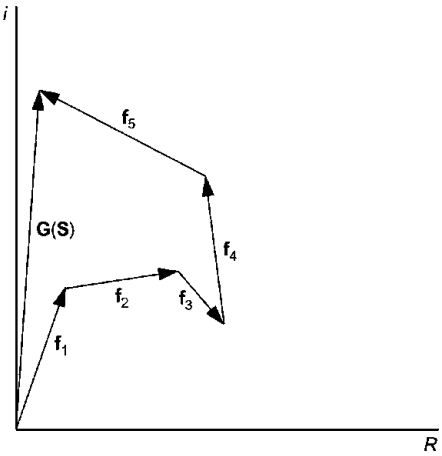

Fig. 24 Vector diagram for the total scattered wave in direction **S** added up for five atoms.

from the unit cell at the origin of the crystal is **G**(**S**). All scatterers in the second unit cell are displaced by the vector **a** relative to the origin, which introduces a corresponding phase factor and reveals for the second unit cell relative to the origin, $\mathbf{G}(\mathbf{S}) \exp 2\pi i\mathbf{aS}$. For the nth unit cell relative to the origin, we obtain $\mathbf{G}(\mathbf{S}) \exp 2\pi i(n-1)\mathbf{aS}$. This sums up for the total wave to Eq. (22):

$$\mathbf{F}(\mathbf{S}) = \sum_{n=1}^{T} \mathbf{G}(\mathbf{S}) \exp 2\pi i(n-1)\mathbf{aS} \quad (22)$$

Generally, **F**(**S**) is of the same order of magnitude as **G**(**S**), and no strong scattering effect is observed (Fig. 25a). However, when $2\pi\ \mathbf{aS} = 2\pi h$ or an integral multiple of 2π or $\mathbf{aS} = h$ (h is an integer), the waves add up constructively to a scattered wave proportional to $T|\ \mathbf{G}(\mathbf{S})|$ (Fig. 25b). $T = 10^5$ for a 1-mm long crystal with a 100-Å lattice constant. The intensity distribution of the scattered waves is concentrated around the values where **aS** is equal to an integer and depends on the number of contributing unit cells. The more unit cells are contributing, the sharper is the concentration of the intensity around these values.

3.3.2 Three-dimensional Crystal

In this case, the unit cell is spanned by the unit cell vectors **a**, **b**, and **c**, and is repeated periodically by the corresponding vector shifts in the respective spatial directions. This means that we will obtain scattered waves of measurable intensities when the three subsequent conditions are fulfilled (Eq. 23):

$$\mathbf{aS} = h;\ \mathbf{bS} = k;\ \mathbf{cS} = l \quad (23)$$

These conditions are known as *Laue equations*.

If we neglect the proportionality constant T, we obtain Eq. (24) for the total scattered wave for a three-dimensional crystal with a unit cell containing N atoms:

$$\mathbf{F}(\mathbf{S}) = \sum_{j=1}^{N} f_j \exp 2\pi i\mathbf{r}_j\mathbf{S} \quad (24)$$

with (Eq. 25)

$$\mathbf{r}_j = \mathbf{a}x_j + \mathbf{b}y_j + \mathbf{c}z_j \quad (25)$$

Hence, we have (Eq. 26 and 27)

$$\mathbf{r}_j\mathbf{S} = x_j\mathbf{aS} + y_j\mathbf{bS} + z_j\mathbf{cS} = hx_j + hy_j + lz_j \quad (26)$$

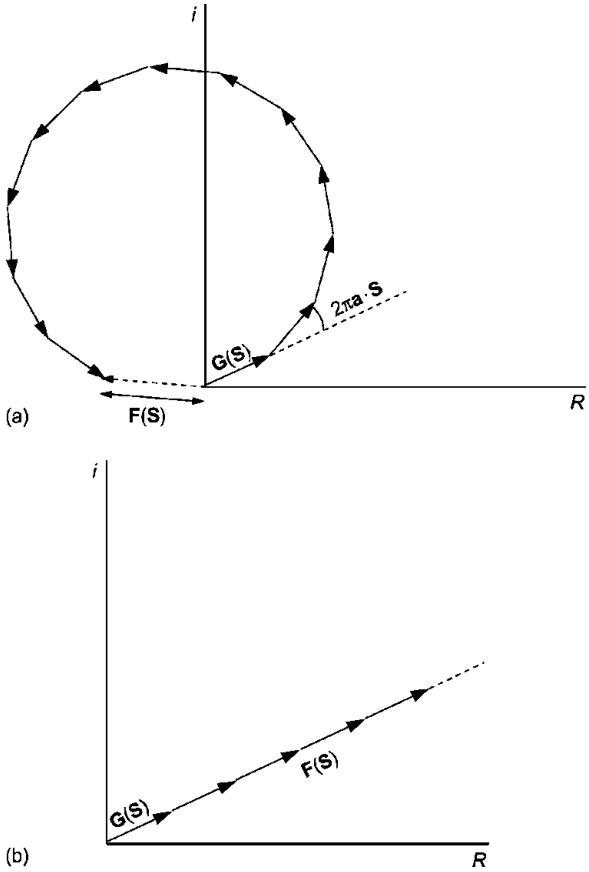

Fig. 25 Vector diagrams displaying the total wave scattered by a molecule in a crystal. (a) The phase differences between waves scattered by adjacent unit cells is $2\pi\,\mathbf{aS}$ and (b) the phase difference is an integral multiple of 2π (adapted from Blundell, T.L., Johnson, L.N. (1976) *Protein Crystallography*, Academic Press, New York).

(from Laue's equation) and

$$\mathbf{F}(hkl) = \sum_{j=1}^{N} f_j \exp 2\pi i(hx_j + hy_j + lz_j)$$
$$= |\mathbf{F}(hkl)| \exp i\alpha(hkl) \qquad (27)$$

with $|\mathbf{F}(hkl)|$ – amplitude and α – phase angle. We obtain the intensity of the scattered wave as the structure factor $\mathbf{F}(hkl)$ multiplied by its complex conjugate value according to (Eq. 28):

$$I(hkl) = \mathbf{F}(hkl)\mathbf{F}^*(hkl)$$
$$= |\mathbf{F}(hkl)|^2 \qquad (28)$$

3.4 The Reciprocal Lattice and Ewald Construction

In section 2.4, we mentioned the usefulness of the concept of the reciprocal lattice

in understanding the diffraction of X-rays from a crystal. Now we have the necessary relations for the derivation of the reciprocal lattice. One can write the scattering vector **S** as Eq.(29):

$$\mathbf{S} = h_x\mathbf{a}^* + k_y\mathbf{b}^* + l_z\mathbf{c}^* \qquad (29)$$

where **S** is a vector in reciprocal space with the metric $\mathbf{a}^*$, $\mathbf{b}^*$, $\mathbf{c}^*$. The relation to the direct space with metric **a, b, c** is still unknown. The vector **S** must obey the Laue equations (Eq. 30):

$$\begin{aligned} a\mathbf{S} &= \mathbf{a}(h_x\mathbf{a}^* + k_y\mathbf{b}^* + l_z\mathbf{c}^*) = h \\ &= h_x\mathbf{a}\mathbf{a}^* + k_y\mathbf{a}\mathbf{b}^* + l_z\mathbf{a}\mathbf{c}^* = h \end{aligned} \qquad (30)$$

This is fulfilled only when $\mathbf{a}\mathbf{a}^* = 1$, $h_x = h$, and $\mathbf{a}\mathbf{b}^*$ and $\mathbf{a}\mathbf{c}^* = 0$. Similar equations can be derived for the other two Laue conditions. Thus, vector **S** is a vector of a lattice in reciprocal space. The relation between direct and reciprocal lattice is given by the following set of nine equations (Eq. 31–39):

$$\mathbf{a}\mathbf{a}^* = 1 \qquad (31)$$

$$\mathbf{b}\mathbf{a}^* = 0 \qquad (32)$$

$$\mathbf{c}\mathbf{a}^* = 0 \qquad (33)$$

$$\mathbf{a}\mathbf{b}^* = 0 \qquad (34)$$

$$\mathbf{b}\mathbf{b}^* = 1 \qquad (35)$$

$$\mathbf{c}\mathbf{b}^* = 0 \qquad (36)$$

$$\mathbf{a}\mathbf{c}^* = 0 \qquad (37)$$

$$\mathbf{b}\mathbf{c}^* = 0 \qquad (38)$$

$$\mathbf{c}\mathbf{c}^* = 1 \qquad (39)$$

It follows from these that $\mathbf{a}^* \perp \mathbf{b}$; $\mathbf{c}$; $\mathbf{b}^* \perp \mathbf{a}$; $\mathbf{c}$; $\mathbf{c}^* \perp \mathbf{a}$; $\mathbf{b}$; and vice versa. The metric relations can also be derived from these relations. It means that the inverse lattice vectors are perpendicular to the plane that is spanned by the two other noninverse lattice vectors. Bragg's law can be derived now by inspection of Fig. 26. The wave vectors for the incident wave $\mathbf{s}_0$ and the scattered wave **S** have the same absolute value of $1/\lambda$. Vector **S** must be a vector of the reciprocal lattice and its absolute value is equal to d^*. From Fig. 26, we obtain Eq. 40 to 42:

$$\sin\theta = \frac{d^*}{2}\lambda \qquad (40)$$

$$\lambda = \frac{2\sin\theta}{d^*} \qquad (41)$$

$$\lambda = 2d\sin\theta \quad \text{for } n = 1 \qquad (42)$$

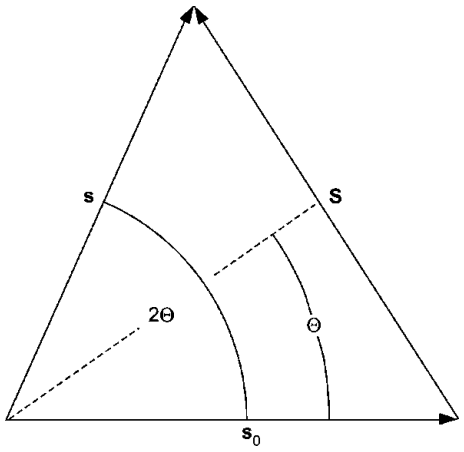

Fig. 26 Geometric representation of diffraction geometry, 2Θ, glance angle; Θ, Bragg angle.

The general equation for Bragg's law is Eq. (43):

$$2d \sin\theta = n\lambda \tag{43}$$

where n is the order of reflection and d is the interplanar distance in the direct lattice.

The Ewald construction is contained in Fig. 20. A sphere of radius $1/\lambda$ is drawn. The origin of the reciprocal lattice is located where the wave vector $\mathbf{s}_0$ ends on the Ewald sphere. A diffracted beam is generated if a reciprocal lattice vector $\mathbf{d}^*_{hkl}$ with an absolute value of $1/d_{hkl}$ cuts the Ewald sphere. The beam is diffracted in the direction of the connection of the origin of the Ewald sphere and the intersection point of the reciprocal lattice point on the Ewald sphere. The diffraction pattern of a lattice is itself a lattice with reciprocal lattice dimensions.

3.5 The Temperature Factor

The thermal motion of the atoms causes a decrease of the scattering power by a factor of $\exp[-B(\sin^2\theta/\lambda^2)]$ with (Eq. 44)

$$B = 8\pi^2\overline{u}^2 \tag{44}$$

where $\overline{u}$ is the mean displacement of the atoms due to the thermal motion. The atomic scattering factor f must be multiplied with this factor. In this model, the thermal motion has been assumed to be isotropic. Therefore, B is denoted as the isotropic temperature factor. In molecules, this is usually not the case and the thermal motion is described by a tensor ellipsoid. Here we obtain a set of six independent anisotropic temperature factors. In protein crystallography, isotropic B values for each atom of the molecules are used normally. The thermal motion of the atoms is one main reason for the falloff of the diffraction intensity especially at higher diffraction angles. This limits the possible recordable number of diffraction spots and, as will be seen later, the resolution of the diffraction experiment.

3.6 Symmetry in Diffraction Patterns

An X-ray diffraction data set from a crystal represents its reciprocal lattice with the corresponding diffraction intensities at the reciprocal lattice points (hkl). As the reciprocal lattice is closely related to its direct partner, it reveals symmetries, lattice properties, and other peculiarities (e.g. systematic extinctions) that are connected to the direct crystal symmetry such as unit cell dimensions and space group. A detailed discussion of this problem is given in Buerger.

In the case of real atomic scattering factors f, the diffraction intensities are centrosymmetric according to Friedel's law (Eq. 45):

$$I(hkl) = I(\overline{hkl}) \tag{45}$$

This is illustrated in Fig. 27(a,b). The square of a complex number is the product of this number by its complex conjugate. This is shown for $\mathbf{F}$ (hkl) in Fig. 27(a) and for $\mathbf{F}(\overline{hkl})$ in Fig. 27(b). The resulting intensities are equal in both cases.

3.7 Electron Density Equation and Phase Problem

Inspection of the equation for the structure factor (Eq. 46)

$$\mathbf{F}(\mathbf{S}) = \sum_{j=1}^{N} f_j \exp 2\pi i \mathbf{r}_j \mathbf{S} = \int_{\text{vol. of unit cell}} \rho(\mathbf{r}) \exp 2\pi i \mathbf{r}\mathbf{S} \mathrm{d}v \tag{46}$$

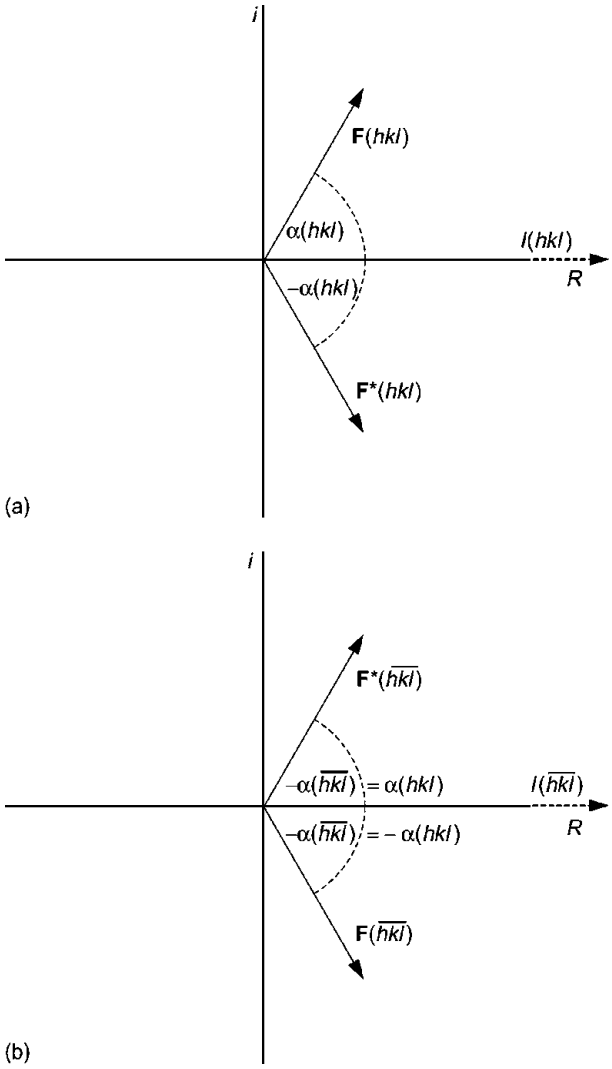

Fig. 27 Diagram illustrating the basis of Friedel's law.

shows that it is the Fourier transform of the electron density ρ (**r**).

The electron density ρ (**r**) is then the inverse Fourier transform of the structure factor **F**(**S**) according to Eq. (47):

$$\rho(\mathbf{r}) = \int_{\substack{\text{vol. of} \\ \text{diffraction space}}} \mathbf{F}(\mathbf{S}) \exp -2\pi i \mathbf{r}\mathbf{S} \mathrm{d}v_s \tag{47}$$

The integration is replaced by summation since **F**(**S**) is not continuous and is nonzero only at the reciprocal lattice points. Hence, we have (Eq. 48)

$$\rho(xyz) = \frac{1}{V} \sum_{h=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} \sum_{l=-\infty}^{\infty} \mathbf{F}(hkl) \times \exp[-2\pi i(hx + ky + lz) \tag{48}$$

Knowing the structure factors (Eq. 49)

$$\mathbf{F}(hkl) = |\mathbf{F}(hkl)| \exp i\alpha(hkl) \qquad (49)$$

one can calculate the electron density distribution in the unit cell and thus determine the atomic positions of the scattering molecule(s). Unfortunately, the measured quantities are only the absolute values $|\mathbf{F}(hkl)|$ of the structure factor. Information on the phase angles $\alpha(hkl)$ is lost during the diffraction experiment. The determination of these phases is the basic problem in any crystal structure determination, and we discuss the methods for solving the phase problem later.

3.8 The Patterson Function

The measured X-ray intensities are proportional to the square of the absolute value of the structure factor according to Eq. (28). Would it be possible to use the intensities directly to calculate from these a function that contains structural information? The answer is "yes." If one calculates a convolution of the electron density with itself, Patterson showed that this is just the Fourier transform of the intensities (Eq. 50):

$$P(uvw) = \int_{\text{vol. of unit cell}} \rho(xyz) \times \rho(x+u, y+v, z+w)\mathrm{d}v \qquad (50)$$

From this, it follows that (Eq. 51)

$$P(\mathbf{u}) = \frac{1}{V}\sum_{\mathbf{h}} F_{\mathbf{h}}^2 \exp -2\pi i\mathbf{hu} \qquad (51)$$

The function $P(\mathbf{u})$ will have maxima if the positions $\mathbf{x}$ and $\mathbf{x}+\mathbf{u}$ correspond to atoms. Thus, we obtain a function that contains the interatomic vectors as maxima. We expect N^2 peaks for N atoms. The maxima are proportional to Z_iZ_j. The Patterson function is a very useful tool to locate atoms when the number of atoms in the asymmetric unit of the unit cell is not too high (e.g. <20) or it contains a subset of heavy atoms among not too many (e.g. <100) light atoms such as C, N, O, or S. Here, the heavy atom–heavy atom vectors are clearly prominent. If a protein with 1000 or a multiple of that light atoms holds one or several heavy atoms per molecule, the signal resulting from the heavy atoms can no longer be resolved. However, when using the method of isomorphous replacement (discussed later), a Patterson function of the heavy atom structure can be calculated, from which it is possible to locate the heavy atoms.

3.9 Integrated Intensity Diffracted by a Crystal

Real crystals are not perfect. They can be regarded as consisting of small blocks of perfect crystals (sizes in the range of 0.1 μm), which have an average tilt angle among each other of 0.1 to 0.5° for protein crystals and which diffract independently of each other. Such a real crystal is denoted a mosaic crystal. The total energy, $\mathrm{E}(\mathbf{h})$, in a diffracted beam for a mosaic crystal rotating with uniform angular velocity w through the reflecting position in a beam of X-rays of incident intensity I_0 is given by Darwin's equation (Eq. 52):

$$\mathrm{E}(\mathbf{h}) = \frac{I_0}{\omega}\lambda^3\frac{e^4}{m^2c^4}p\frac{LAV_x}{V^2}|\mathbf{F}(\mathbf{h})|^2 \qquad (52)$$

where λ = wavelength of X-rays, e = electronic charge, m = mass of electron, c = velocity of light, p = polarization factor, L = Lorentz factor (geometrical factor taking into account the relative time each reflection spends in the reflection position), A = absorption factor, V = volume

of the unit cell, and V_x = irradiated crystal volume.

Owing to the mosaicity (0.1–0.5°), each reflection has a corresponding reflection width. The integrated intensity equation is valid under the assumption that apart from ordinary absorption, the incident intensity, I_0, is constant within the crystal (kinematic theory of X-ray diffraction) and the mosaic blocks are so small that no multiple scattering occurs within an individual mosaic block. The integrated intensity depends on λ to the third power. Increasing the wavelength causes appreciably stronger diffraction intensities but is accompanied by larger absorption. Copper Kα radiation with a wavelength of 1.5418 Å is an optimal choice for protein crystallography when using X-ray generator sources. Also important is the dependence of the integrated intensity on the unit cell volume V by its negative second power. Doubling of the unit cell volume with twice as many molecules, taking into account the increase in $|\mathbf{F(h)}|^2$ by having now $2n$ molecules per unit cell, reduces the average intensity for the reflected beams by a factor of two. In Eq. (52), $(\lambda^3/\omega V^2) \times (e^4/m^2c^4) \times V_x \times I_0$ is a constant for a given experiment. The corrected intensity on a relative scale $I(\mathbf{h})$ is obtained from Eq. (53):

$$I(\mathbf{h}) = \frac{E(\mathbf{h})}{p \times L \times A} \tag{53}$$

3.10 Intensities on an Absolute Scale

The corrected intensity on a relative scale $I(\mathbf{h})$ can be converted to an intensity given by Eq. (54)

$$I(abs, \mathbf{h}) = \mathbf{F(h)F(h)}^* = |\mathbf{F(h)}|^2 \tag{54}$$

on an absolute scale by applying a so-called Wilson plot. The basis for this plot is an equation that connects the average intensity on an absolute scale with the average intensity on a relative scale by a scale factor C and considers the isotropic thermal motion of the scattering atoms by the temperature factor given in Eq. (44). This is written in the form of Eq. (55):

$$\ln \frac{\overline{I(\mathbf{h})}}{\sum_j (f_j)^2} = \ln C - 2B\frac{\sin^2\theta}{\lambda^2} \tag{55}$$

This is the equation of a straight line. B, the overall temperature factor, and C, the scale factor, can be obtained by plotting $\ln \overline{I(\mathbf{h})} / \sum_j (f_j)^2$ against $(\sin^2\theta)/\lambda^2$.

3.11 Resolution of the Structure Determination

The concept of resolution in X-ray diffraction has the same meaning as the concept in image formation in the optical microscope. After the Abbe theory, we obtain Eq. (56):

$$d_m = \frac{\lambda}{2NA} \tag{56}$$

where NA is the numerical aperture of the objective lens. In protein crystallography, the nominal resolution of an electron density map is expressed in d_m, the minimum interplanar spacing for which Fs are included in the Fourier series. The maximum attainable resolution at a given wavelength is $\lambda/2$. For Cu Kα radiation, it is 0.7709 Å and would suffice to determine protein structures at atomic resolution (the distance of a carbon–carbon single bond is about 1.5 Å). However, usually the thermal vibrations of the atoms in

a protein crystal are so high that the diffraction data cannot be observed to the full theoretical resolution limit. The polypeptide chain fold can be determined at a resolution of better than 3.5 Å. A medium-resolution structure is in the resolution range of 3.0 to 2.2 Å, and makes the amino acid side chains clearly visible. A high-resolution structure has a nominal resolution better than 2.2 Å and can be as good as 1.2 Å. In such structures, the main-chain carbonyl oxygens become visible as prominent bumps and at a resolution better than 2.0 Å, aromatic side chains acquire a hole in the middle of their ring systems. For some very well diffracting crystals from small proteins, diffraction data extending to resolutions below 1.2 Å could be collected with synchrotron radiation. Such structures reveal real atomic resolution where each atom is visible as an isolated maximum in the electron density map.

3.12 Diffraction Data Evaluation

The analysis and reduction of diffraction data from a single crystal consists of seven main steps: (1) visualization and preliminary analysis of the raw, unprocessed data; (2) indexing of the diffraction patterns; (3) refinement of the crystal and detector parameters; (4) integration of the diffraction spots; (5) finding the relative scale factors between measurements; (6) precise refinement of crystal parameters using the whole data set; and (7) merging and statistical analysis of the measurements related by space-group symmetry. When using electronic area detectors with short readout times such as CCD or MWPC detectors, it is possible to collect diffraction images with small rotational increments (0.05–0.2°). In this case, the reflection profile over the crystal rotation angle can be registered, giving a three-dimensional picture of the spot. The evaluation of such diffraction data can be done with computer programs MADNES, XDS, the San Diego programs and related programs XENGEN, and X-GEN. IP systems with their longer readout times are operated in a film-like mode with rotational increments of 0.5 to 2.0°. Here, mainly the program systems MOSFLM and Denzo are applied. The most important developments in the data evaluation of macromolecular diffraction measurements are autoindexing, profile fitting, transformation of data to a reciprocal-space coordinate system, and demonstration that a single rotation image contains all of the information necessary to derive the diffraction intensities from that image.

Scaling, merging, and statistical analysis of the intensity data are either done with corresponding programs of the CCP4 program suite or with Scalepack. The principles of these operations are given in the manuals for these programs. With modern data-collection methods, the completeness should approach 100% (including the low-resolution data, which are very important for molecular replacement), the ratio $I/\sigma(I)$ should be significant even for the highest resolution shell, and undue emphasis should not be given to the reliability factor for merging the data (R-merge) unless factors such as multiplicity are taken into account. Nowadays, it is customary using synchrotron radiation techniques and fast CCD detectors to collect as much data as possible (before radiation damage becomes significant) in order to produce good statistics.

3.13 Solvent Content of Protein Crystals

The Matthews parameter V_M, which is defined according to Eq. (57):

$$V_M = \frac{V_{\text{unit cell}}}{M_{\text{Prot}}} \tag{57}$$

where $V_{\text{unit cell}}$ is the volume of the unit cell and M_{Prot} is the molecular mass of the protein in the unit cell, has values that are in the range 1.6 to 3.5 $\text{Å}^3\ \text{Da}^{-1}$ for proteins. This allows a rough estimation of the number of molecules in the unit cell. Furthermore, V_M can be used for the assessment of the solvent content of a protein crystal. Calling V_{Prot} the crystal volume occupied by the protein, V'_P its fraction with respect to the total crystal volume V, and M_{Prot} the mass of protein in the cell, we obtain Eq. (58):

$$V'_P = \frac{V_{\text{Prot}}}{V} = \frac{V_{\text{Prot}}/M_{\text{Prot}}}{M_{\text{Prot}}/V} \tag{58}$$

The first term is the specific volume of the protein, the second the reciprocal of V_M and, remembering that the molecular weight is expressed in daltons, we have Eq. (59):

$$V'_P = \frac{1.6604}{d_{\text{Prot}} V_M} \tag{59}$$

Taking 1.35 g cm^{-3} as the protein density, we obtain as a first approximation Eq. (60) and (61):

$$V'_P \approx \frac{1.23}{V_M} \tag{60}$$

$$V'_{\text{Solv}} \approx 1 - V'_P \tag{61}$$

The solvent content in a protein crystal may vary from 75 to 40%.

4 Methods for Solving the Phase Problem

4.1 Isomorphous Replacement

4.1.1 Preparation of Heavy Metal Derivatives

If one can attach one or several heavy metal atoms at defined binding site(s) to the protein molecules without disturbing the crystalline order, one can use such isomorphous heavy atom derivatives for the phase determination. The lack of isomorphism can be monitored by a change in the unit cell parameters compared with the native crystal and a deterioration of the quality of the diffraction pattern. The preparation of heavy atom derivatives is undertaken by soaking the crystals in mother liquor containing the dissolved heavy metal compound. Soaking times may be in the range from several minutes to months. Concentrations of the heavy metal compound may vary from tenths of millimolar to 50 mM. Favorite heavy atoms are Hg, Pt, U, Pb, Au, rare earth metals, and so on. Potential ligands can be classified as hard and soft ligands according to Pearson. Hard ligands are electronegative and undergo electrostatic interactions. In proteins, such ligands are glutamate, aspartate, terminal carboxylates, hydroxyls of serines and threonines, and in the buffer acetate, citrate, and phosphate. Soft ligands are polarizable and form covalent bonds such as cysteine, cystine, methionine, and histidine in proteins, and Cl^-, Br^-, I^-, S-ligands, CN^-, and imidazole in the buffer solution.

Metals are classified according to their preference for hard or soft ligands. Class (a) metals bind preferentially to hard ligands. They comprise the cations of A-metals such as alkali and alkaline earth metals, the lanthanides, some actinides,

and groups IIIA, IVA, and VA of the transition metals. Class (b) metals are rather soft and polarizable and can form covalent bonds to soft ligands. They include heavy metals at the end of the transition metal groups such as Hg, Pt, and Au. Thus, in the protein, the class (b) metals Hg, Pt, and Au and complex compounds of them bind to soft ligands such as cysteine, histidine, or methionine and the class (a) metals U and Pb to hard ligands such as the carboxylate groups of glutamate or aspartate.

4.1.2 Single Isomorphous Replacement

The structure factor $\mathbf{F}_{PH}$ for the heavy atom derivative structure (Fig. 28) becomes (Eq. 62)

$$\mathbf{F}_{PH} = \mathbf{F}_P + \mathbf{F}_H \tag{62}$$

where $\mathbf{F}_P$ = structure factor of the native protein and $\mathbf{F}_H$ = contribution of the heavy atoms to the structure factor of the derivative. The isomorphous differences, $F_{PH} - F_P$, which can be calculated from experimental intensity data sets of the native and derivative protein, correspond to the distance CB in Fig. 28, and are given by Eq. (63):

$$F_{PH} - F_P = F_H \cos(\alpha_{PH} - \alpha_H) - 2F_P \sin^2\left(\frac{\alpha_P - \alpha_{PH}}{2}\right) \tag{63}$$

If F_H is small compared with F_P and F_{PH}, the sine term will be very small and we have (Eq. 64)

$$F_{PH} - F_P \approx F_H \cos(\alpha_{PH} - \alpha_H) \tag{64}$$

When vectors $\mathbf{F}_P$ and $\mathbf{F}_H$ are collinear, then (Eq. 65)

$$|\mathbf{F}_{PH} - \mathbf{F}_P| = F_H \tag{65}$$

The square of the isomorphous differences, $F_{PH} - F_P$, can be used as coefficients in a Patterson synthesis. We get

$$\begin{aligned}(F_{PH} - F_P)^2 &= 4F_P^2 \sin^4\left(\frac{\alpha_P - \alpha_{PH}}{2}\right) && \text{(i)}\\ &\quad + F_H^2 \cos^2(\alpha_{PH} - \alpha_H) && \text{(ii)}\\ &\quad - 4F_P F_H \sin^2\left(\frac{\alpha_P - \alpha_{PH}}{2}\right) \times \cos(\alpha_{PH} - \alpha_H) && \text{(iii)}\end{aligned} \tag{66}$$

It is a theorem of Fourier theory that the Fourier transform of the sum

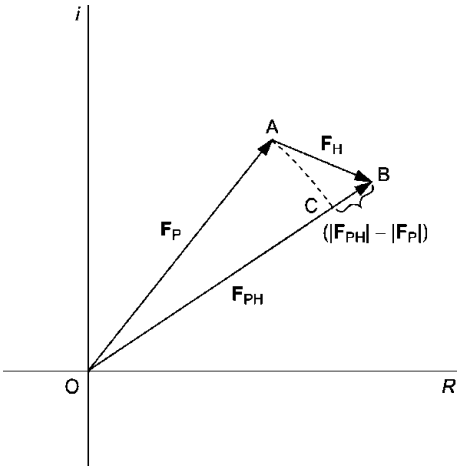

Fig. 28 Vector diagram for the vector addition of the structure factor of the native protein $\mathbf{F}_P$ and the heavy atom contribution $\mathbf{F}_H$ to the heavy atom derivative structure factor $\mathbf{F}_{PH}$.

of Fourier coefficients is equal to the sum of the Fourier transforms of the individual Fourier coefficients. Here, there are three different terms. $(\alpha_P - \alpha_{PH})$ is small if F_H is small, and term (i), which gives the protein–protein interaction will be of low weight. The transform of term (iii) is zero if sufficient terms are included. However, if $F_H \ll F_P$, $(\alpha_P - \alpha_{PH})$ is effectively random, and term (ii) will give heavy atom vectors with half the expected peak heights (Eq. 67)

$$F_H^2 \cos^2(\alpha_{PH} - \alpha_H) = \frac{1}{2}F_H^2 + \frac{1}{2}F_H^2 \cos 2(\alpha_{PH} - \alpha_H) \quad (67)$$

with the second term on the right contributing only noise to the Patterson map because the angles α_{PH} and α_H are not correlated. Such an isomorphous heavy atom difference Patterson map allows the determination of the positions of the heavy metals on the condition of isomorphism and a not-too-large heavy atom partial structure. The interpretation of these difference Patterson maps is undertaken by vector verification routines, which are part of the CCP4 program suite. In these routines, the asymmetric unit of the unit cell is systematically scanned by calculating on each scan point the corresponding heavy atom–heavy atom vectors, determining their peak height in the Patterson map and evaluating a meaningful correlation value (e.g. the sum of the correlated maxima). Prominent heavy atom sites should show up with high correlation values.

It is important to know what intensity changes are generated by the attachment of heavy atoms to the macromolecule. According to Crick and Magdoff, the relative root-mean-square intensity change is given by Eq. (68) for centric reflections:

$$\frac{\sqrt{\overline{(\Delta I)^2}}}{\overline{I_P}} = 2 \times \sqrt{\frac{\overline{I_H}}{\overline{I_P}}} \quad (68)$$

and by Eq. (69) for acentric reflections:

$$\frac{\sqrt{\overline{(\Delta I)^2}}}{\overline{I_P}} = \sqrt{2} \times \sqrt{\frac{\overline{I_H}}{\overline{I_P}}} \quad (69)$$

where $\overline{I_H}$ is the average intensity of the reflections if the unit cell were to contain the heavy atoms only and $\overline{I_P}$ is the average intensity of the reflections of the native protein. Attaching one mercury atom ($Z = 80$) to a macromolecule with varying molecular mass and assuming 100% occupancy gives the following average relative changes in intensity: 0.51 for 14 000 Da, 0.25 for 56 000 Da, 0.18 for 112 000 Da, 0.13 for 224 000 Da, and 0.09 for 448 000 Da. From this estimation it is evident that with increasing molecular mass more heavy atoms or for large molecular masses heavy metal clusters such as $Ta_6Br_{12}^{2+}$ must be introduced to generate intensity changes that can be statistically measured (precision for intensity measurements between 5 and 10%) and which are sufficient for the phasing.

The phase calculation for single isomorphous replacement can be seen from the so-called Harker construction for this case (Fig. 29). $\mathbf{F}_H$, which can be calculated from the known heavy atom positions, is drawn in its negative direction from the origin O ending at point A. Circles are drawn with radii F_P and F_{PH} from points O and A respectively. The connections of the intersection points of both circles B and C with origin O determine two possible phases for $\mathbf{F}_P$. This means that the single isomorphous replacement leaves an ambiguity in the phase determination for the acentric reflections.

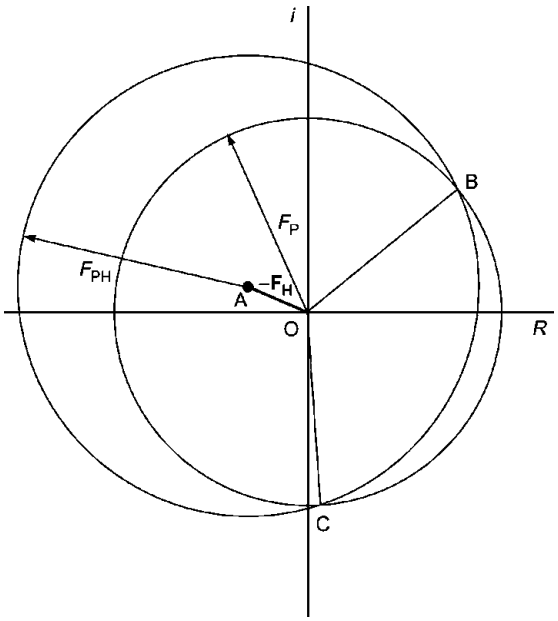

Fig. 29 Harker construction for the phase calculation by the method of single isomorphous replacement.

4.1.3 **Multiple Isomorphous Replacement**

The phase ambiguity can be overcome if two or more isomorphous heavy atom derivatives are used, which exhibit different heavy atom partial structures. In Fig. 30, the Harker construction for two different heavy atom derivatives is shown. In addition to Fig. 29, $-\mathbf{F}_{H2}$ is drawn from the origin O and a third circle with radius F_{PH2} is inserted around its endpoint B. The

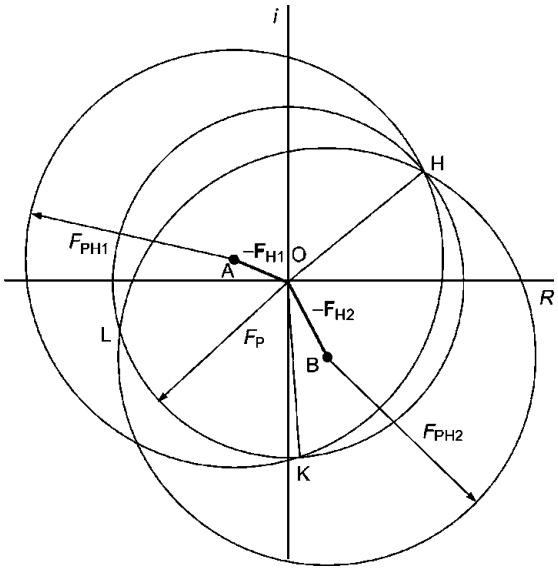

Fig. 30 Harker construction for the phase calculation by the method of MIR for two different heavy atom derivatives PH1 and PH2.

intersection point, H, of all three circles determines the protein phase, α_P. In the case of n isomorphous derivatives, there are $n+1$ circles, which have one common intersection point whose connection to origin O determines the protein phase, α_P.

4.2 Anomalous Scattering

4.2.1 Theoretical Background

So far, in the normal Thomson scattering of X-rays, the electrons in the atom have been treated as free electrons that vibrate as a dipole-oscillator in response to the incident electromagnetic radiation and generate elastic scattering of the X-rays. However, the electrons are bound to atomic orbitals in atoms, and this treatment is valid only if the frequency ω of the incident radiation is large compared to any natural absorption frequency ω_{kn} of the scattering atom. For the light atoms in biological macromolecules (H, C, N, O, S, P) with frequency ω of the used radiation (in the range of 0.4 to 3.5 Å), this condition is fulfilled and these atoms scatter normally. For heavier elements, the assumption $\omega \gg \omega_{kn}$ is no longer valid, and the frequency ω may be higher for some and lower for other absorption frequencies. If ω is equal to an absorption frequency ω_{kn}, absorption of radiation will occur, which is manifested by the ejection of a photoelectron with an energy corresponding to the ionization energy for this electron. This transition goes to a state in the continuous region because the discrete energy states are all occupied in the atom. The absorption frequencies for the K, L, or M shells are connected with the corresponding absorption edges, which are characterized by a sharp drop in the absorption curve (absorption vs λ) at the edge position. It is evident that the scattering from the electrons with their resonance frequencies close or equal to the frequency of the incident radiation will deliver a special contribution, which is called *anomalous scattering*.

The classical treatment is briefly outlined. It is assumed that the atoms scatter as if they contain electric dipole-oscillators having certain definite natural frequencies. The classical differential equation of the motion of a particle of mass m and charge e in an alternating electric field $\mathbf{E} = \mathbf{E}_0 e^{i\omega t}$ is Eq. (70):

$$\ddot{\mathbf{x}} + k\dot{\mathbf{x}} + \omega_s^2 \mathbf{x} = \frac{e\mathbf{E}_0}{m} e^{i\omega t} \qquad (70)$$

where the damping factor, k, is proportional to the velocity of the displayed charge and ω_s is the natural circular frequency of the dipole if the charge is displaced. The steady state solution for this equation for the moment of the dipole that executes forced oscillations of frequency under the action of the incident wave is Eq. (71):

$$\mathbf{M} = e\mathbf{x} = \frac{e^2}{m} \frac{\mathbf{E}_0 e^{i\omega t}}{\omega_s^2 - \omega^2 + ik\omega} \qquad (71)$$

The amplitude A of the scattered wave at unit distance in the equatorial plane is given by Eq. (72):

$$A = \frac{e^2}{mc^2} \frac{\omega^2 E_0}{\omega_s^2 - \omega^2 + ik\omega} \qquad (72)$$

The scattering factor of the dipole, f, is now defined as the ratio of the amplitude scattered by the oscillator to that scattered by a free classical electron under the same conditions. This amplitude at unit distance and in the equatorial plane is given by Eq. (73):

$$A' = -\frac{e^2}{mc^2} E_0 \qquad (73)$$

Hence, we obtain Eq. (74) for f:

$$f = \frac{\omega^2}{\omega^2 - \omega_s^2 - ik\omega} \tag{74}$$

If f is positive, the scattered wave has a phase difference of π with respect to the primary beam (introduced by the negative sign in the equation for A'). If $\omega \gg \omega_s$, f is unity. In the case of $\omega \ll \omega_s$, f is negative, and the dipole then scatters a wave in phase with the primary beam.

Equation (74) can be split into real and imaginary parts so that we obtain Eq. (75):

$$f = f' + if'' \tag{75}$$

with (Eqs. 76 and 77)

$$f' = \frac{\omega^2(\omega^2 - \omega_s^2)}{(\omega^2 - \omega_s^2)^2 + k^2\omega^2} \tag{76}$$

$$f'' = \frac{k\omega^3}{(\omega^2 - \omega_s^2)^2 + k^2\omega^2} \tag{77}$$

We now extend this for an atom consisting of s electrons, each acting as a dipole-oscillator with oscillator strength $g(s)$ and resonance frequency ω_s. We have to multiply the contribution for each electron by $g(s)$ and form the sum over all electrons. For the total real part of the atomic scattering factor, we obtain Eq. (78):

$$f' = \sum_s \frac{g(s)\omega^2}{\omega^2 - \omega_s^2} \tag{78}$$

which assumes that ω is not very nearly equal to ω_s, and a small damping. f' can be written as Eq. (79):

$$f' = f_0 + \Delta f' = \sum_s g(s) + \sum_s \frac{g(s)\omega_s^2}{\omega^2 - \omega_s^2} \tag{79}$$

For free electrons, we have $\omega_s = 0$ and $f' = f_0 = \sum_s g(s)$. The real part of the increment of the scattering factor is due to the binding of electrons. $\Delta f'$ is the dispersion component of the anomalous scattering.

If ω is comparable to ω_s but slightly greater, $ik\omega$ must not be neglected. f becomes complex (Eq. 80):

$$f = f' + if'' = f_0 + \Delta f' + i\Delta f'' \tag{80}$$

The imaginary part lags $\pi/2$ behind the primary wave, that is it is always $\pi/2$ in front of the scattered wave. $\Delta f''$ is known as the absorption component of the anomalous scattering. In the quantum mechanical treatment of the problem, the oscillator strengths are calculated from the atomic wave functions. Hönl, in theoretical work, used hydrogen-like atomic wave functions. In the frame of this approach, to each natural dipole frequency ω_s in the classical expression, there corresponds in the quantum expression a frequency ω_{kn}, which is the Bohr frequency associated with the transition of the atom from the energy state k to the state n in which it is supposed to remain during the scattering. Modern quantum mechanical calculations of anomalous scattering factors on isolated atoms, based on relativistic Dirac–Slater wave functions, have been carried out by Cromer and Liberman. It follows from the theory of the anomalous scattering of X-rays that f_0 is real, independent of the wavelength of the incident X-rays but dependent on the scattering angle. $\Delta f'$ and $\Delta f''$ depend on the wavelength, λ, of the incident radiation but are virtually independent of the scattering angle.

4.2.2 Experimental Determination

$\Delta f''$ is related to the atomic absorption coefficient μ_0 by Eq. (81):

$$\Delta f''(\omega) = \frac{mc\omega}{4\pi}\mu(\omega_0) \tag{81}$$

$\Delta f'$ can now be calculated by the Kramers–Kronig transformation (Eq. 82):

$$\Delta f''(\omega) = \frac{2}{\pi}\int_0^\infty \frac{\omega' \Delta f''(\omega')}{\omega^2 - \omega'^2} d\omega' \quad (82)$$

As fluorescence is closely related to absorption, fluorescence measurements varying the X-ray radiation frequency are used to determine the frequency dependence of the dispersive components of the different chemical elements. Instead of the radiation frequency ω, the radiation is often characterized by its wavelength, λ, or photon energy, E. The dispersion correction terms $\Delta f'$ and $\Delta f''$ are often simply denoted f' and f''. Figure 31 shows the anomalous scattering factors near the absorption K edge of selenium from a crystal of *E. coli* selenomethionyl thioredoxin. The spectrum was measured with tunable synchrotron radiation. Apart from the "white line" feature at the absorption edge, f'' drops by about 4 electrons, approaching the edge from the short wavelength side; $\Delta f'$ exhibits a symmetrical drop of -8 electrons around the edge. Similar values can be observed at the K edges for Fe, Cu, Zn, and Br, whose wavelengths all lie in the range 0.9 to 1.8 Å, which is well suited for biological macromolecular X-ray diffraction experiments. For other interesting heavy atoms such as Sm, Ho, Yb, W, Os, Pt, and Hg, the LII (Sm) or LIII edges are in this range. Here, the effects are even greater. Considerably larger changes are found for several lanthanides, such as Yb, where the minimum f' is -33 electrons and the maximum f'' is 35 electrons.

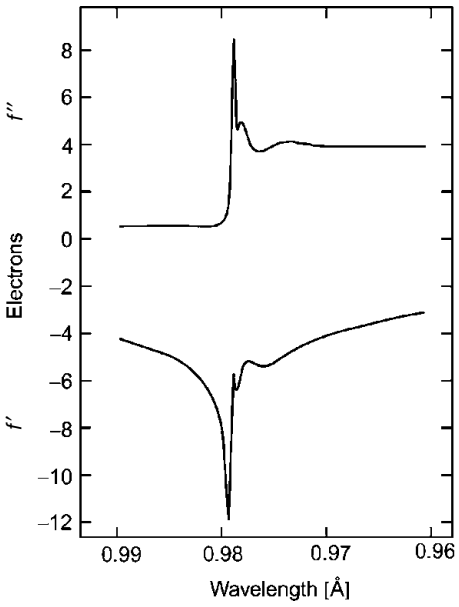

Fig. 31 Anomalous scattering factors near the absorption K edge of selenium from a crystal of *E. coli* selenomethionyl thioredoxin. (Reproduced by permission of Academic Press, Inc., from Hendrickson, W.A., Ogata, C.M. (1997) *Methods Enzymol.* **276**, 494–523.)

4.2.3 Breakdown of Friedel's Law

Under the assumption that the crystal contains a group of anomalous scatterers, one can separate the contributions from the distinctive components of the scattering factor according to Hendrickson and Ogata to obtain Eq. (83):

$$^{\lambda}\mathbf{F}(\mathbf{h}) = {}^{\circ}\mathbf{F}_{\mathrm{N}}(\mathbf{h}) + {}^{\circ}\mathbf{F}_{\mathrm{A}}(\mathbf{h}) + {}^{\lambda}\mathbf{F}'_{\mathrm{A}}(\mathbf{h}) + i^{\lambda}\mathbf{F}''_{\mathrm{A}}(\mathbf{h}) \quad (83)$$

where $^{\circ}\mathbf{F}_{\mathrm{N}}$ is the contribution of the normal scatterers and $^{\circ}\mathbf{F}_{\mathrm{A}}$, $^{\lambda}\mathbf{F}'_{\mathrm{A}}$, and $^{\lambda}\mathbf{F}''_{\mathrm{A}}$ are the contributions for the corresponding components of the complex atomic form factor. For the centrosymmetric reflection, we obtain Eq. (84):

$$\mathbf{F}(-\mathbf{h}) = {}^{\circ}\mathbf{F}_{\mathrm{N}}(-\mathbf{h}) + {}^{\circ}\mathbf{F}_{\mathrm{A}}(-\mathbf{h}) + {}^{\lambda}\mathbf{F}'_{\mathrm{A}}(-\mathbf{h}) + i^{\lambda}\mathbf{F}''_{\mathrm{A}}(-\mathbf{h}) \quad (84)$$

The geometric presentation for both structure factors is given in Fig. 32. The

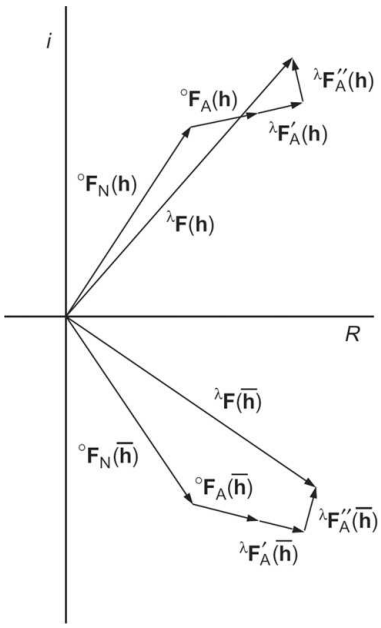

Fig. 32 Vector diagram explaining the breakdown of Friedel's law.

inversion of the sign of **h** causes a negative phase angle for all contributions where the components of the scattering factor are real. For the f''-dependent part, this is also valid, but owing to the imaginary factor i, this vector has to be constructed with a phase angle $+\pi/2$ with respect to ${}^{\circ}\mathbf{F}_A(-\mathbf{h})$ and ${}^{\lambda}\mathbf{F}'_A(-\mathbf{h})$. The resultant absolute values for ${}^{\lambda}\mathbf{F}(\mathbf{h})$ and ${}^{\lambda}\mathbf{F}(-\mathbf{h})$ are no longer equal, which means that their intensities (square of the amplitude) are different (breakdown of Friedel's law).

4.2.4 Anomalous Difference Patterson Map

One can show that (Eq. 85)

$$ {}^{\lambda}F(\mathbf{h}) - {}^{\lambda}F(-\mathbf{h}) \approx \frac{2}{k}[{}^{\circ}\mathrm{F}_A(\mathbf{h}) + {}^{\lambda}F'_A(\mathbf{h})]\sin(\alpha_{\mathbf{h}} - \alpha_A) \qquad (85) $$

where $\alpha_{\mathbf{h}}$ is the phase angle of ${}^{\lambda}\mathbf{F}(\mathbf{h})$, α_A the phase angle of the anomalous scatterers, and (Eq. 86)

$$ k = \frac{{}^{\circ}\mathrm{F}_A(\mathbf{h}) + {}^{\lambda}F'_A(\mathbf{h})}{{}^{\lambda}F''_A(\mathbf{h})} \qquad (86) $$

As coefficients for an anomalous difference Patterson map, we obtain Eq. (87):

$$ \Delta F^2_{\mathrm{ano}} = [{}^{\lambda}F(\mathbf{h}) - {}^{\lambda}F(-\mathbf{h})]^2 \sim \frac{4}{k^2}[{}^{\circ}\mathrm{F}_A(\mathbf{h}) + {}^{\lambda}F'_A(\mathbf{h})]^2 \sin^2(\alpha_{\mathbf{h}} - \alpha_A) \qquad (87) $$

The ΔF_{ano}s will be maximal if the phase angle α_A is perpendicular to the phase angle $\alpha_{\mathbf{h}}$ and zero if both vectors are collinear, which is opposite to the MIR case. The anomalous Patterson map contains peaks of the anomalous scatterers with heights proportional to half of $(4/k^2)[{}^{\circ}\mathrm{F}_A(\mathbf{h}) + {}^{\lambda}F'_A(\mathbf{h})]^2$ owing to the $\sin^2$ term and is therefore suited to determine the structure of the anomalous scatterers.

4.2.5 Phasing Including Anomalous Scattering Information

The combination of anomalous scattering information with isomorphous replacement permits the unequivocal determination of the protein phases, as shown in Fig. 33. Using the anomalous scattering information alone gives two possible solutions for the protein phase characterized by the intersection points H and L in Fig. 33. Combining it with the corresponding intensities from the native protein without the anomalous scatterers leaves only one solution for the protein phase (vector O-H in Fig. 33). The case in Fig. 33 is called *single isomorphous replacement anomalous scattering* (*SIRAS*). Having n isomorphous heavy atom derivatives, each with anomalous scattering contributions, the Harker

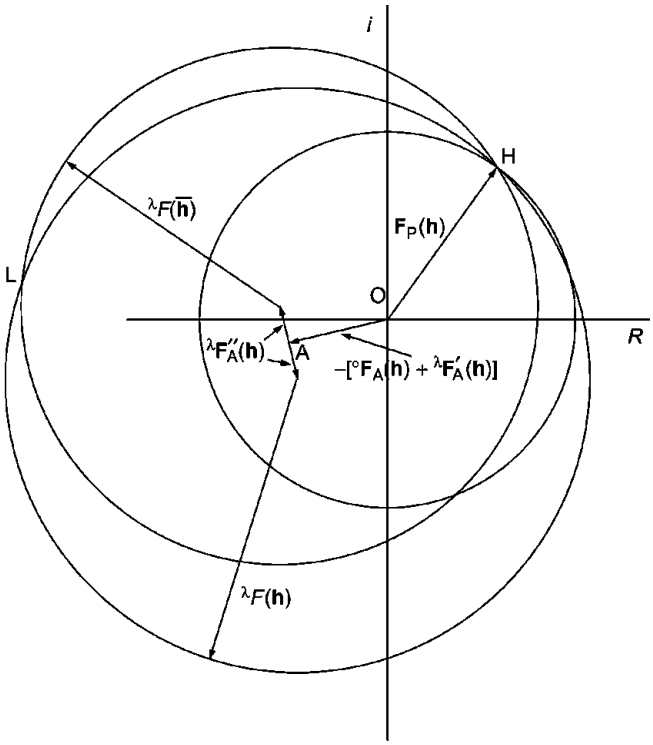

Fig. 33 Harker construction illustrating the phase determination combining information from anomalous scattering and isomorphous replacement.

construction can be extended for this situation, and the phasing method is then designated as multiple isomorphous replacement anomalous scattering (MIRAS).

4.2.6 Multiwavelength Anomalous Diffraction Technique

During the last few years, the MAD technique has matured to be a routine method and has led to a revolution in biological macromolecular crystallography. If there are one or a few anomalous scatterers in the biological macromolecule, it is possible to determine the whole spatial structure from one crystal (exact isomorphism) by the MAD technique. The anomalous scatterers may be intrinsic as in metalloproteins (e.g. Fe, Zn, Cu, Mo, Mn) or exogenous (e.g. Hg in a heavy atom derivative or Se in selenomethionyl proteins). A prerequisite for the MAD technique is well-diffracting crystals (resolution better than 2.8 Å) because the anomalous components of the atomic form factor are virtually independent of the diffraction angle and acquire increasing weight with increasing scattering angle. This advantageous property together with exact isomorphism serves for the determination of good phases down to the full resolution, and leads to the production of excellent experimental MAD-phased electron density maps. A typical MAD experiment is carried out at three different

wavelengths (tunable synchrotron radiation), at minimum f' and maximum f'' at the absorption edge of the anomalous scatterer(s), and at a remote wavelength where anomalous scattering effects are small.

The basic equations for the MAD technique as formulated by Hendrickson and Ogata are as follows. Equation (83) can be written as Eq. (88):

$$^{\lambda}\mathbf{F}(\mathbf{h}) = {}^{\circ}\mathbf{F}_{\mathrm{T}}(\mathbf{h}) + {}^{\lambda}\mathbf{F}_{\mathrm{A}}(\mathbf{h}) + i\,{}^{\lambda}\mathbf{F}''_{\mathrm{A}}(\mathbf{h}) \tag{88}$$

where (Eq. 89)

$$^{\circ}\mathbf{F}_{\mathrm{T}} = {}^{\circ}\mathbf{F}_{\mathrm{N}} + {}^{\circ}\mathbf{F}_{\mathrm{A}} \tag{89}$$

with subscript T for the totality of atoms in the structure.

Furthermore, we have Eqs. (90) to (93):

$$^{\circ}\mathbf{F}_{\mathrm{T}}(f^{\circ}) = {}^{\circ}\mathrm{F}_{\mathrm{T}} \exp(i\,{}^{\circ}\phi_{\mathrm{T}}) \tag{90}$$

$$^{\circ}\mathbf{F}_{\mathrm{A}}(f^{\circ}) = {}^{\circ}\mathrm{F}_{\mathrm{A}} \exp(i\,{}^{\circ}\phi_{\mathrm{A}}) \tag{91}$$

$$^{\lambda}\mathbf{F}'_{\mathrm{A}} = f(f') \tag{92}$$

$$^{\lambda}\mathbf{F}''_{\mathrm{A}} = f(f'') \tag{93}$$

In the common case of a single kind of anomalous scatterer, we obtain Eqs. (94) and (95):

$$^{\lambda}\mathbf{F}'_{\mathrm{A}} = \frac{f'(\lambda)}{f^{\circ}}\,{}^{\circ}\mathbf{F}_{\mathrm{A}} \tag{94}$$

$$^{\lambda}\mathbf{F}''_{\mathrm{A}} = \frac{f''(\lambda)}{f^{\circ}}\,{}^{\circ}\mathbf{F}_{\mathrm{A}} \tag{95}$$

Separating the experimentally observable squared amplitude into wavelength-dependent and wavelength-independent terms gives Eq. (96):

$$\begin{aligned} {}^{\lambda}F(\pm\mathbf{h})^2 = {}& {}^{\circ}\mathrm{F}_{\mathrm{T}}^2 + a(\lambda)\,{}^{\circ}\mathrm{F}_{\mathrm{A}}^2 \\ & + b(\lambda)\,{}^{\circ}\mathrm{F}_{\mathrm{T}}\,{}^{\circ}\mathrm{F}_{\mathrm{A}} \cos({}^{\circ}\phi_{\mathrm{T}} - {}^{\circ}\phi_{\mathrm{A}}) \\ & \pm c(\lambda)\,{}^{\circ}\mathrm{F}_{\mathrm{T}}\,{}^{\circ}\mathrm{F}_{\mathrm{A}} \sin({}^{\circ}\phi_{\mathrm{T}} - {}^{\circ}\phi_{\mathrm{A}}) \end{aligned} \tag{96}$$

with (Eqs. 97–99)

$$a(\lambda) = \frac{f'^2 + f''^2}{f^{\circ 2}} \tag{97}$$

$$b(\lambda) = 2\frac{f'}{f^{\circ}} \tag{98}$$

$$c(\lambda) = 2\frac{f''}{f^{\circ}} \tag{99}$$

The derivation of the formula for ${}^{\lambda}F(\mathbf{h})^2$ is illustrated in detail. ${}^{\lambda}F(\mathbf{h})^2$ is obtained from the triangle formed by the vectors ${}^{\lambda}\mathbf{F}(\mathbf{h})$, ${}^{\circ}\mathbf{F}_{\mathrm{T}}(\mathbf{h})$, and $\mathbf{a}$ (Fig. 34) by use of the cosine rule. The absolute values of the vectors are represented in italics, and the relevant angle is $(180^{\circ} - {}^{\circ}\phi_{\mathrm{A}} - \delta)$. We get

$$\begin{aligned} {}^{\lambda}F(\mathbf{h})^2 = {}& {}^{\circ}\mathrm{F}_{\mathrm{T}}^2 + \left(\frac{f'^2 + f''^2}{f^{\circ 2}}\right) {}^{\circ}\mathrm{F}_{\mathrm{A}}^2 - 2 \\ & \times {}^{\circ}\mathrm{F}_{\mathrm{T}} \times \left(\frac{f'^2 + f''^2}{f^{\circ 2}}\right)^{1/2} \times {}^{\circ}\mathrm{F}_{\mathrm{A}} \\ & \times \cos(\pi - \delta - {}^{\circ}\phi_{\mathrm{A}} + {}^{\circ}\phi_{\mathrm{T}}) \end{aligned} \tag{100}$$

The cosine term in Eq. (100) can be obtained using some basic trigonometry:

$$\begin{aligned} & \cos(\pi + ({}^{\circ}\phi_{\mathrm{T}} - {}^{\circ}\phi_{\mathrm{A}} - \delta)) \\ & \quad = -\cos({}^{\circ}\phi_{\mathrm{T}} - {}^{\circ}\phi_{\mathrm{A}} - \delta) \end{aligned} \tag{101}$$

$$\begin{aligned} & \cos(({}^{\circ}\phi_{\mathrm{T}} - {}^{\circ}\phi_{\mathrm{A}}) - \delta) = \cos({}^{\circ}\phi_{\mathrm{T}} - {}^{\circ}\phi_{\mathrm{A}}) \\ & \quad \times \cos\delta + \sin({}^{\circ}\phi_{\mathrm{T}} - {}^{\circ}\phi_{\mathrm{A}}) \times \sin\delta \end{aligned} \tag{102}$$

with

$$\begin{aligned} \cos\delta = {} & \frac{\left(\frac{f'}{f^{\circ}}\right) \times {}^{\circ}\mathrm{F}_{\mathrm{A}}}{\left(\frac{f'^2 + f''^2}{f^{\circ 2}}\right)^{1/2}} \\ & \times {}^{\circ}\mathrm{F}_{\mathrm{A}} = \frac{\left(\frac{f'}{f^{\circ}}\right)}{\left(\frac{f'^2 + f''^2}{f^{\circ 2}}\right)^{1/2}} \end{aligned} \tag{103}$$

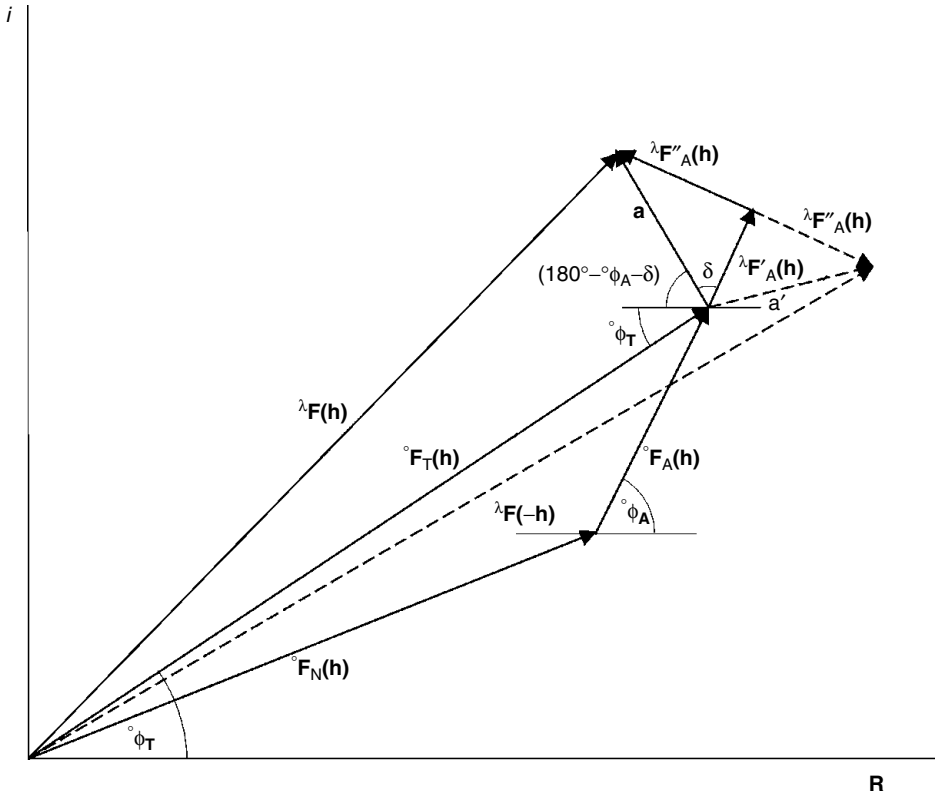

Fig. 34 Schematic drawing of structure factors of a biological macromolecule that contains one kind of anomalous scatterer.

$$\sin\delta = \frac{\left(\frac{f''}{f^\circ}\right) \times {}^\circ\mathrm{F_A}}{\left(\frac{f'^2 + f''^2}{f^\circ 2}\right)^{1/2}}$$

$$\times\ {}^\circ\mathrm{F_A} = \frac{\left(\frac{f''}{f^\circ}\right)}{\left(\frac{f'^2 + f''^2}{f^{\circ 2}}\right)^{1/2}} \qquad (104)$$

Substituting this in Eq. 99, we obtain the expression for ${}^\lambda F(\mathbf{h})^2$. ${}^\lambda F(-\mathbf{h})^2$ is determined from the triangle formed by the vectors ${}^\lambda\mathbf{F}(-\mathbf{h})$, ${}^\circ\mathbf{F}_\mathrm{T}(\mathbf{h})$, and $\mathbf{a}'$ (Fig. 34) using a similar approach. Maximum anomalous scattering effects can be expected in intensity differences of reflections that would be equal for exclusively normal scattering. This is the case for Friedel pairs, $\mathbf{h}$ and $-\mathbf{h}$, or their rotational symmetry partners, and the relation for such differences is given in Eq. (85). Of further interest are dispersive differences between structure amplitudes at different wavelengths, Eq. (105):

$$\Delta F_{\Delta\lambda} \equiv {}^{\lambda i}F(\mathbf{h}) - {}^{\lambda j}F(\mathbf{h}) \qquad (105)$$

The anomalous or dispersive intensity differences can be used to determine the structure of the anomalous scatterers. The methods are the same as for isomorphous replacement. They include vector

verification procedures of difference Patterson maps or direct methods programs such as Shake and Bake and SHELXD.

4.2.7 Determination of the Absolute Configuration

As anomalous scattering destroys the centrosymmetry of the diffraction data, this effect can be used to determine the absolute configuration of chiral biological macromolecules. The most common method is to calculate protein phases on the basis of both hands of the heavy atom or anomalous scatterer structures and check the quality of the relevant electron density map that should be better for the correct hand. Furthermore, secondary structural elements in proteins (consisting of L-amino acids) such as α-helices should be right handed.

4.3 Patterson Search Methods (Molecular Replacement)

If the structures of molecules are similar (virtually identical) or contain a major similar part, this can be used to determine the crystal structure of the related molecule if the structure of the other molecule is known. This is done by systematically exploring the Patterson function of the crystal structure to be determined with the Patterson function of the search model. Let us first consider some important features of the Patterson function. The relation between two identical molecules in the search crystal structure (Fig. 35a) can generally be formulated as Eq. (106):

$$\mathbf{X}_2 = [C]\mathbf{X}_1 + \mathbf{d} \qquad (106)$$

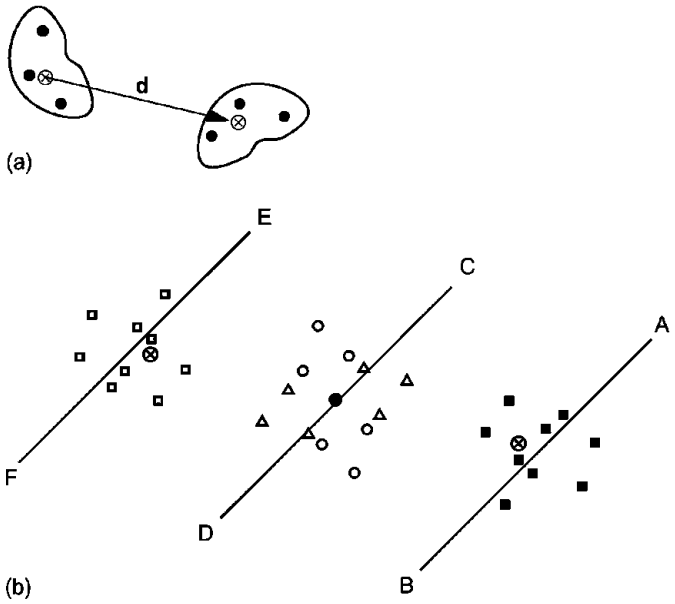

Fig. 35 Patterson function of two identical molecules separated by the spatial movement given in Eq. (106). (a) Positions of the two molecules; (b) interatomic vectors of structure in (a). △, ○, intramolecular vectors of the left and right molecule; □, ■, intermolecular vectors.

Equivalent positions $\mathbf{X}_1$ in molecule 1 are at positions $\mathbf{X}_2$ of molecule 2. [*C*] is the rotation matrix and **d** is the translation vector of the movement of the molecule. Fig. 35(b) shows the Patterson function belonging to the molecular arrangement in Fig. 35(a). It is evident that around the origin, vectors are assembled that are intramolecular, whereas the vectors around lines AB and EF are intermolecular. The intramolecular vectors depend on the molecule orientation only and, therefore, can be used for its determination. Once the orientation of the molecule(s) has been elucidated, this can be used to reveal the translation of the molecule(s) by analyzing the intermolecular vector part of the Patterson function. The distinction between intra- and intermolecular vector sets and exploiting them for orientation and translation determination was given by Hoppe. The extension to protein crystallography and the first mathematical formulation of the rotation and translation functions were given by Rossmann and Blow.

4.3.1 Rotation Function

The intramolecular vectors are arranged in a volume around the origin of the Patterson function with a radius equal to the dimension of the molecule. The rotational search is then carried out in this volume u. The search Patterson (deduced either from the search model or from the crystal Patterson itself) is rotated to any possible rotational orientation $\mathbf{X}_2$, characterized by three rotational angles α, β, γ, which may be defined in different ways (polar angles, Eulerian angles, etc.). At each angular position, the actual functional values are correlated with those of the crystal Patterson all through the volume u and integrated over this volume. The correlation function may be the sum or the product of each corresponding pair of values. Rossmann and Blow proposed a product function, and the rotation function for this case is given by Eq. (107):

$$R(\alpha, \beta, \gamma) = \int_u P_2(\mathbf{X}_2 P_1(\mathbf{X}_1) \mathrm{d}\mathbf{X}_1 \quad (107)$$

The function has maxima if the intramolecular vector sets are coincident. The calculation can be carried out in both direct and reciprocal space.

The self-rotation function is a special form of the rotation function. If an asymmetric unit contains more than one copy of a molecule, the rotation matrix between the molecules can be determined by a self-rotation function. Here, the crystal Patterson is rotated against itself, and the integration is taken over the volume u around the origin in the same manner. The identical molecules may have an arbitrary orientation to each other or they may be related by local or the so-called noncrystallographic symmetries. Searching for local rotation axes is done best in a polar angle system. The search Patterson is brought into each polar orientation and then rotated around the angle value for the local axis being sought, for example 120° for a threefold local axis.

4.3.2 Translation Function

Once the orientation of the molecule(s) has been determined, the translation of the molecule(s) can be obtained from a translation function. The model Patterson $P_2(\mathbf{u})$ revealed from the model in the correct orientation is calculated for different translations $\mathbf{t}$ and correlated with the crystal Patterson $P_1(\mathbf{u})$. The translation function proposed by Crowther and Blow has the form shown in Eq. (108):

$$T(\mathbf{t}) = \int P_1(\mathbf{u}) P_2(\mathbf{u}, \mathbf{t}) \mathrm{d}\mathbf{u} \quad (108)$$

$T(\mathbf{t})$ reveals a maximum peak at the correct translation $\mathbf{t}$ if the center of gravity of the search model was at the origin for $\mathbf{t} = 0$.

4.3.3 Computer Programs for Molecular Replacement

An early program for molecular replacement, working in direct space, was written by Huber. Nowadays, several program packages are available, either being exclusively dedicated to the molecular replacement technique or having integrated relevant modules. Pure molecular replacement programs are, for example, AMORE and GLRF. The rotational and translational search starting from the search model is fully automated in AMORE and includes a final rigid body refinement of each proposed solution. GLRF offers different types of rotation and translation functions, all operating in reciprocal space, and a Patterson correlation refinement. A peculiarity of the GLRF program is the locked rotation function. This function takes into account the possible noncrystallographic symmetries and is an average of n independent rotation functions with an improved peak-to-noise ratio. Frequently used program packages including molecular replacement modules are the CCP4 program suite, CNS, and PROTEIN.

4.4 Phase Calculation

4.4.1 Refinement of Heavy Atom Parameters

Before the protein phases can be calculated, it is necessary to refine the heavy atom parameters. These are the coordinates x, y, z, the temperature factor (either isotropic or anisotropic), and the occupancy. The refinement modifies the parameters in such a way that $|\mathbf{F}_{PH}(obs)|$ becomes as close as possible to $|\mathbf{F}_{PH}(calc)|$. Using the method of least squares, the refinement according to Rossmann minimizes Eq. (109):

$$\varepsilon = \sum_{\mathbf{h}} w(\mathbf{h})[(F_{PH} - F_P)^2 - kF^2_{H\ calc}]^2 \tag{109}$$

where k is a scaling factor to correct F^2_{Hcalc} to a theoretically more acceptable value because according to Eq. (64), $\mathbf{F}_{PH} - \mathbf{F}_P$ and $\mathbf{F}_H$ have approximately the same length when $\mathbf{F}_{PH}$, $\mathbf{F}_P$, and $\mathbf{F}_H$ point in the same direction. The probability for this case will be high if the difference between F_{PH} and F_P is large. An improvement can be obtained if the contribution from the anomalous scattering is included.

For the parameter refinement of anomalous scattering sites, the differences between the observed and calculated structure factor amplitudes for $^{\circ}F_A$ are subjected to minimization. Another approach treats the anomalous or dispersive contributions as in MIR phasing.

From the refined heavy atom parameters, preliminary protein phase angles α_P can be obtained as shown in the corresponding Harker construction. A further refinement of the heavy atom parameters can be achieved by the "lack of closure" method, incorporating this knowledge. The definition of this "lack of closure" ε is illustrated in Fig. 36(a) and (b). In the case of perfect isomorphism, the vector triangle $\mathbf{F}_P + \mathbf{F}_H = \mathbf{F}_{PH}$ closes exactly (Fig. 36a). In practice, this condition will not be fulfilled, and a difference ε between the observed F_{PH} and the calculated F_{PH} will remain (Fig. 36b). $F_{PH}(calc)$ can be obtained from the triangle OAB (Fig. 36b)

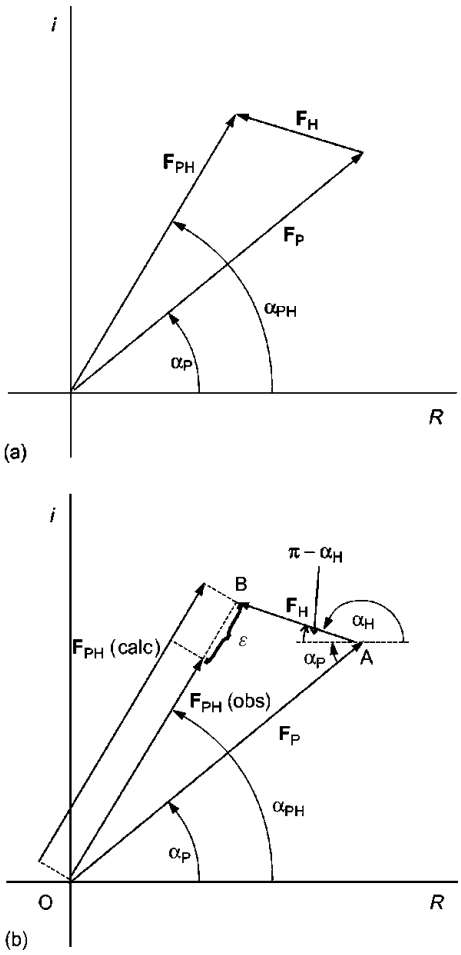

Fig. 36 Definition of "lack of closure." (a) Perfect isomorphism; (b) usually, the observed and calculated values for $\mathbf{F}_{PH}$ differ by the "lack of closure" ε.

with the cosine rule (Eq. 110):

$$F_{PH} = [F_P^2 + F_H^2 + 2F_P \times F_H \cos(\alpha_H - \alpha_P)]^{1/2} \quad (110)$$

The function that is minimized by the least-squares method is Eq. (111):

$$E_j = \sum_{\mathbf{h}} m_{\mathbf{h}} \varepsilon_j(\mathbf{h})^2 \quad (111)$$

where (Eq. (112))

$$\varepsilon_j = k_j F_{PHj}(\text{obs}) - F_{PHj}(\text{calc}) \quad (112)$$

is the "lack of closure" for the heavy atom derivative j, k_j is a scaling factor, and $m_{\mathbf{h}}$ is a weighting factor.

4.4.2 Protein Phases

As the structure factor amplitudes F_P, F_{PH}, F_H, and α_H are known, the protein phase angle α_P can be calculated. For the single isomorphous replacement situation (Fig. 28), ε is zero only for the two protein phase angles α_P where the two circles for F_P and F_{PH} intersect. In practice, all these observed quantities exhibit errors. For the treatment of these errors, it is assumed that all errors are in $\mathbf{F}_{PH}$ and that both $\mathbf{F}_H$ and $\mathbf{F}_P$ are error free. For each protein phase angle α, $\varepsilon(\alpha)$ is calculated. The smaller $\varepsilon(\alpha)$ is, the higher is the probability of a correct phase angle α. For each reflection of a derivative j, a Gaussian probability distribution is assumed for ε according to Eq. (113):

$$P(\alpha) = P(\varepsilon) = N \exp\left[-\frac{\varepsilon^2(\alpha)}{2E^2}\right] \quad (113)$$

where N is a normalization factor and E^2 is the mean square value of ε. Small values of E are related to probability curves with sharp peaks and well-determined phase angles, and the opposite is true for large E values. Such phase-angle probability curves can be calculated for each individual reflection and derivative. For single isomorphous replacement, this curve is symmetric with two high peaks corresponding to the two possible solutions for α_P. We obtain the total probability for each reflection with contributions from n heavy atom derivatives by multiplying the

individual probabilities (Eq. 114):

$$P(\alpha) = \prod_{j=1}^{n} P_j(\alpha) = N' \exp\left[-\sum_j \frac{\varepsilon_j^2(\alpha)}{2E_j^2}\right] \tag{114}$$

These curves will be nonsymmetric with one or several maxima (see Fig. 37a and b).

The question arises of which phases should be taken in the electron density equation to calculate the best electron density function. An immediate guess would be to use the phases where $P(\alpha)$ has the highest value. This approach would be appropriate for unimodal distributions but not for bimodal distributions. Blow and Crick derived the phase value that must be applied under the assumption that the mean square error in electron density over the unit cell is minimal. For one reflection, this is given by Eq. (115):

$$(\Delta\rho^2) = \frac{1}{V^2}(\mathbf{F}_s - \mathbf{F}_t)^2 \tag{115}$$

where $\mathbf{F}_t$ is the true factor and $\mathbf{F}_s$ is the structure factor applied in the Fourier synthesis. The mean square error is then obtained as Eq. (116):

$$(\Delta\rho^2) = \frac{1}{V^2}\frac{\int_{\alpha=0}^{2\pi}(\mathbf{F}_s - F\exp i\alpha)^2 P(\alpha)\mathrm{d}\alpha}{\int_{\alpha=0}^{2\pi} P(\alpha)\mathrm{d}\alpha} \tag{116}$$

$\mathbf{F}_t$ has a phase probability of $P(\alpha)$ and has been given as $\mathbf{F}_t = F\exp i\alpha$. It can be shown that the numerator integral in Eq. (116) is minimal if (Eq. 117)

$$\mathbf{F}_{s(best)} = F\frac{\int_{\alpha=0}^{2\pi}\exp(i\alpha)P(\alpha)\mathrm{d}(\alpha)}{\int_{\alpha=0}^{2\pi} P(\alpha)\mathrm{d}\alpha} = mF\exp(i\alpha_{best}) \tag{117}$$

Equation (117) corresponds to the center of gravity of the probability distribution with polar coordinates (mF, α_{best}), where m is defined as magnitude of $\mathbf{m}$ given by Eq. (118):

$$\mathbf{m} = \frac{\int_{\alpha=0}^{2\pi} P(\alpha)\exp(i\alpha)\mathrm{d}\alpha}{\int_{\alpha=0}^{2\pi} P(\alpha)\mathrm{d}\alpha} \tag{118}$$

This magnitude of $\mathbf{m}$ is equivalent to a weighting function and is designated the ''figure of merit.'' The electron density map calculated with mF and α_{best} is known

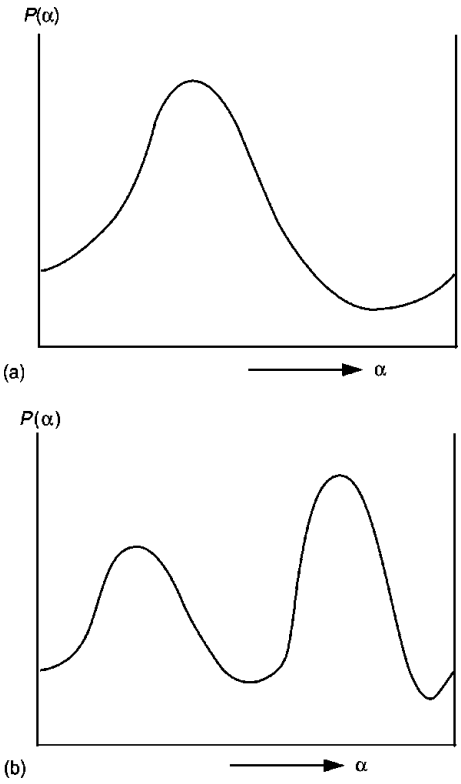

Fig. 37 Total probability curves $P(\alpha)$ for two different reflections: (a) for one derivative; (b) for more than one derivative.

as *best Fourier* and should represent a Fourier map with minimum least-squares error from the true Fourier map.

For the total error of the ''best Fourier,'' Eq. (119) has been derived:

$$(\Delta\rho^2) = \frac{1}{V^2}\sum_{\mathbf{h}} F^2(\mathbf{h})(1 - m^2) \quad (119)$$

The order of magnitude of this error may be illustrated by the example of the structure determination of lysozyme. The root-mean-square error in the Fourier synthesis was 0.35 e $Å^{-3}$, with values of 2.0-Å resolution for the diffraction data and a mean ''figure of merit'' of 0.6.

The program systems CCP4 and PROTEIN contain all routines necessary to calculate protein phases according to the MIRAS technique and a number of different kinds of Fourier maps. Alternative probabilistic approaches for the phase calculation are used in programs MLPHARE and SHARP. Both programs can also carry out MAD phasing. The MADSYS program is based on the algebraic approach outlined in the MAD section of this contribution and executes all tasks of a MAD analysis from scaling to phase-angle calculation.

4.5 Phase Improvement

With the methods so far described, an experimental electron density map can be calculated, and if its quality is high enough, the atomic model can be constructed. However, there are methods for further phase improvement available, which may be applied in general or depending on the given prerequisites. Such phase improvement routines have been used routinely over the last 10 years and have had a large impact on the advancement of biological macromolecular crystallography.

4.5.1 Solvent Flattening

Protein crystals have a solvent content of 75 to 40%. In a highly refined protein crystal structure, the solvent space between the molecules is rather flat owing to the dynamic nature of this region. Usually, the initial experimental starting phases are of lower quality than the final ones and as a result, the solvent region (if the molecular boundaries can be identified) contains noise peaks. It is now obvious to set the noisy solvent space to a low constant value and calculate new improved phases by Fourier back-transforming this corrected electron density map. However, it is evident that the definition of the molecular boundaries will be tedious and depend on the quality of the electron density map. Wang has proposed an automatic procedure that smooths the electron density to define the protein region. This smoothed electron density map is traced against a threshold value that separates this map into molecule and solvent space according to their ratio of volumes in the unit cell. The space inside the molecular envelope is polished to avoid internal voids. Now, a new electron density map is calculated using the observed structure factor amplitudes and the phases revealed from the solvent corrected map. The solvent corrected map is obtained by setting all electron density values inside the molecular envelope to those of the initial map and all values outside the envelope to a low constant value. These phases from the solvent flattening procedure can be combined with the MIR or MAD phases. This procedure can be repeated in several iterative cycles because after each cycle of solvent flattening, the quality of the electron density map is improved. There are no prerequisites for the application of the method of solvent flattening. It is evident that solvent flattening is most

effective for crystals with a high solvent content.

4.5.2 Histogram Matching

Histogram matching is a technique emanating from image processing. In the application to electron density maps, it is assumed that a high-quality protein crystal structure has a characteristic frequency distribution of electron density, which serves as a standard reference distribution for other electron density maps. Such maps of lower quality exhibit a frequency distribution of electron density, which deviates from the standard distribution. The electron density map of low quality is then scaled in such a way that its frequency distribution of electron density now corresponds to the standard distribution. Histogram matching is normally used together with solvent flattening and is incorporated into the density modification programs SQUASH and DM from the CCP4 program package.

4.5.3 Molecular Averaging

If there is more than one identical subunit in the asymmetric unit of the crystal, molecular averaging can be used to improve the protein phases. The spatial relations between the single identical subunits in the asymmetric unit may be determined by Patterson search methods or from the arrangement of the heavy atoms or anomalous scatterers. The spatial relation between the identical subunits can be improper (the relevant spatial movement consists of a rotation about an unsymmetrical angle value and a translation component) or proper (the spatial movements form a symmetry group that is composed of rotational symmetry elements only). Such additional symmetries are called *noncrystallographic* or *local*, and there are no limitations concerning the Zähligkeit of the symmetry axes (e.g. five-, seven-, and higherfold axes are allowed). It is evident that averaging about the different related subunits, whose electron density should be equal in each subunit, must result in an improved electron density map and therefore in improved protein phases. Molecular averaging is best done in direct space and several programs (e.g. RAVE or MAIN) are available.

The procedure of molecular averaging is composed of several steps. First, the molecular envelope must be determined from the initial electron density map or from a molecular model that, for example, has been obtained from molecular replacement. Next, the particular electron density averaging between the related subunits is performed. This is followed by the reconstitution of the complete crystal unit cell with the averaged electron density. The space outside the molecular envelope is flattened. This map is then Fourier back-transformed. The obtained phase angles can either be taken directly or combined with known phase information to calculate a new and improved electron density map. This cycle can be repeated several times until convergence of the electron density map improvement has been reached. It is very useful to refine the local symmetry operations after every macrocycle of molecular averaging. Furthermore, molecular averaging can be applied if proteins crystallize in more than one crystal form.

Molecular averaging is especially efficient if a high noncrystallographic symmetry is present as in virus structures, but the averaging over two related subunits alone (the lowest case of local symmetry) can give a considerable improvement.

In special cases where high noncrystallographic symmetry exists and the phase information extends to low resolution only, cyclic molecular averaging can be used to extend the phase angles to the full resolution of the native protein. This was first shown in the structure analysis of hemocyanin from *Panulirus interruptus*. It is extensively used in the analysis of icosahedral structures and for large molecular assemblies.

4.5.4 Phase Combination

In the course of a crystal structure analysis of a biological macromolecule, phase information from different sources may be available, such as information from isomorphous replacement, anomalous scattering, partial structures, solvent flattening, and molecular averaging. An overall phase improvement can be expected when these factors are combined, and a useful method to do this was proposed by Hendrickson and Lattman. The probability curve for each reflection is written in an exponential form as Eq. (120):

$$P_s(\alpha) = N_s \exp(K_s + A_s \cos\alpha + B_s \sin\alpha + C_s \cos 2\alpha + D_s \sin 2\alpha) \quad (120)$$

Subscript s stands for the source from which the phase information has been derived. K_s and the coefficients A_s, B_s, C_s, and D_s depend on the structure factor amplitudes and other magnitudes, for example, the estimated standard deviation of the errors in the derivative intensity, but are independent of the protein phase angles α. The overall probability function $P(\alpha)$ is obtained by a multiplication of the individual phase probabilities, and this turns out to be a simple addition of all K_s and of the related coefficients in the exponential term. We obtain Eq. (121):

$$\begin{aligned} P(\alpha) &= \prod_s P_s(\alpha) \\ &= N' \exp\left[\sum_s K_s + \left(\sum_s A_s\right)\cos\alpha + \left(\sum_s B_s\right)\sin\alpha + \left(\sum_s C_s\right)\cos 2\alpha + \left(\sum_s D_s\right)\sin 2\alpha\right] \end{aligned} \quad (121)$$

K_s and the coefficients A_s to D_s have special expressions for each source of phase information.

4.6 Difference Fourier Technique

Supposing that one has solved the crystal structure of a biological macromolecule and has isomorphous crystals of this macromolecule, which contain small structural changes caused by a substrate-analog or inhibitor binding, a metal removal or replacement or a local mutation of one or several amino acids. Then, these structural changes can be determined by the difference Fourier technique. The difference Fourier map is calculated with the differences between the observed structure factor amplitudes of the slightly altered molecule $F_{DERI}(\text{obs})$ and the native molecule $F_{NATI}(\text{obs})$ as Fourier coefficients and the phase angles of the native molecule α_{NATI} as phases according to Eq. (122):

$$\rho_{DERI} - \rho_{NATI} \cong \frac{1}{V}\sum_{\mathbf{h}} m[F_{DERI}(\text{obs}) - F_{NATII}(\text{obs}) \times \exp(i\alpha_{NATI}) \times \exp(-2\pi i \mathbf{hx})] \quad (122)$$

where m may be the figure of merit or another weighting scheme. The difference Fourier map can alternatively be calculated with coefficients $F_{\mathrm{DERI}}(\mathrm{obs}) - F_{\mathrm{DERI}}(\mathrm{calc})$ and phases $\alpha_{\mathrm{DERI}}(\mathrm{calc})$. $F_{\mathrm{DERI}}(\mathrm{calc})$ and $\alpha_{\mathrm{DERI}}(\mathrm{calc})$ do not include the unknown contribution of the structural change.

Figure 38(a) and (b) illustrate the relation for the structure factors involved in the difference Fourier technique. We assume that the structural change is small. If F_{NATI} is large, the structure factor amplitude of the structural change F_{SC} will be small compared to F_{NATI}, and α_{DERI} will be close to α_{NATI}. This is no longer valid if F_{NATI} is small. Now, F_{SC} is comparable to F_{NATI}, and α_{DERI} may deviate considerably from α_{NATI}. This implies the necessity to introduce a weighting scheme that scales down the contributions where the probability is high that α_{NATI} differs appreciably from the correct phase angle. Various weighting schemes have been elaborated such as those of Sim and Read. The weighting scheme of Sim has the following form (Eq. 123):

$$w = \frac{I_1(X)}{I_0(X)} \tag{123}$$

for acentric reflections and (Eq. 124)

$$w = \tanh \frac{X}{2} \tag{124}$$

for centric reflection with (Eq. 125)

$$X = \frac{2F_{\mathrm{DERI}} \times F_{\mathrm{NATI}}}{\sum_{1}^{n} f_j^2} \tag{125}$$

$I_0(X)$ and $I_1(X)$ are modified Bessel functions of zeroth and first order respectively. These equations and weighting schemes can also be used for the calculation of OMIT maps (where parts of the model have been omitted from the structure factor evaluation) or when a complete structure must be developed from a known partial model. F_{DERI} must be replaced by the observed structure factor F, F_{NATI} by the structure factor of the known or included part of the model F_{K}, and α_{NATI} by the phase angle α_{K} of the known or included part of the model.

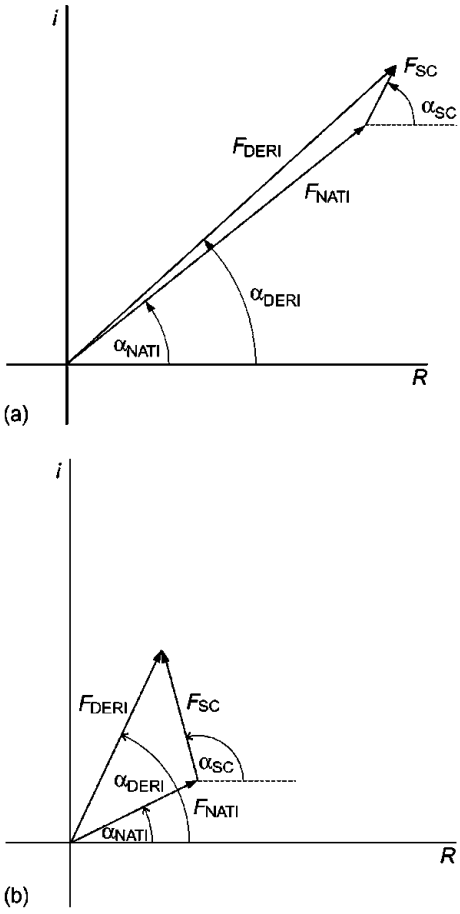

Fig. 38 Vector diagrams illustrating different situations (a) and (b) in the difference Fourier technique for the involved structure factors.

5
Model Building and Refinement

5.1
Model Building

Once the quality of the MIRAS or MAD maps is good enough, model building can be started. This is done on a computer graphics system, and the main modeling programs are O and TURBO-FRODO. An interesting alternative is the program MAIN, which additionally contains routines for molecular averaging, molecular docking, and other features. The visualization of the relevant electron density map on the computer graphics system is done as cagelike structures. For this purpose, the standard deviation from the mean value of the map is calculated, and the cagelike structure is built up for a given contour level (normally 1.0 σ). The first task in a *de novo* protein crystal structure analysis is to localize the trace of the polypeptide chain. This can be assisted by routines for automatic chain tracing such as the bones routine, an auxiliary program of O. Such automatic chain-tracing programs generate a skeleton of the electron density map. This representation was introduced by Greer. When the trace of the polypeptide chain has been identified, the atomic model can be built into the electron density. The atomic model is represented as sticks, connecting the atomic centers of bonded atoms. The individual building blocks (amino acids) of the protein molecule can be generated, interactively manipulated (e.g. linked with each other, moved, rotated, etc.), and fitted into the corresponding part of the electron density map. The geometry of the atomic model is regularized according to protein standard geometries.

The success of model building depends on the quality and resolution of the experimental electron density map. Usually, the quality of the electron density map is not so good that the complete model can be constructed in one cycle. In this case, the partial atomic model is refined crystallographically against the observed structure factor amplitudes. This phase information can be used directly to calculate a new electron density map commonly with $2F_{obs} - F_{calc}$ Fourier coefficient amplitudes. This kind of map is the sum of a normal F_{obs} Fourier and a difference Fourier synthesis. It displays the atomic model with normal weight and indicates errors in the model by its contribution of the difference Fourier map. The parallel determination and inspection of a difference Fourier map are also very helpful. As already mentioned, the model phases can be combined with phases present from other sources or incorporated in procedures of phase improvement. A further model-building cycle can be started with such new and improved electron density maps. After several cycles of model building and crystallographic refinement, the atomic model will be so well defined that the solvent structure of internally bound solvent molecules can be developed. The atomic model is complete now and the biochemical interpretation can be started.

5.2
Crystallographic Refinement

The structural model has to be subjected to a refinement procedure. In practical macromolecular crystallography, one does not always have atomic resolution. Therefore, the single atoms cannot be treated as moving independently. They must be refined using energy or stereochemistry restraints, taking care to

maintain a reasonable stereochemistry of the macromolecule. There exist different approaches to structure refinement of macromolecules. The minimization of a potential energy function E together with a diffraction term D according to Eq. (126):

$$S = E + D \tag{126}$$

where (Eqs. 127 and 128)

$$\begin{aligned} E = &\sum k_{\mathrm{b}}[b_{j(\mathrm{calc})} - b_j^0]^2 \\ &+ \sum k_\tau[\tau_{j(\mathrm{calc})} - \tau_j^0]^2 \\ &+ \sum k_\Theta[1 + \cos(m\Theta_k + \delta] \\ &+ \sum (Ar^{-12} + Br^{-6}) \end{aligned} \tag{127}$$

$$D = \sum_i w_i[F_{i(\mathrm{obs})} - kF_{i(\mathrm{calc})}]^2 \tag{128}$$

is applied in the programs EREF and CNS, which are now used frequently. The four terms of the right-hand side of E describe bond, valence angle, dihedral torsion angle, and nonbonded interactions, k_{b} is the bond stretching constant, k_τ is the bond angle bending force constant, k_Θ is the torsional barrier, m and δ are the periodicity and the phase of the barrier, A and B are the repulsive and long-range nonbonded parameters, D is the crystallographic contribution with w_i a weighting factor, F_{obs} is the observed structure factor, F_{calc} is the calculated structure factor, and k is a scaling factor. Programs TNT and PROLSQ use stereochemically restrained least-squares refinement. For both refinement schemes, parameters are employed that were derived from small molecule crystal structures of amino acids, small peptides, nucleic acids, sugars, fatty acids, cofactors, and so on. If noncrystallographic symmetry is present, a corresponding term may be introduced in the energy or stereochemistry part of the expression to be minimized. It is possible to divide the structural model into several individual parts and refine these parts as rigid bodies. This is especially useful with solutions from molecular replacement.

A measure of the quality of the crystallographic model is calculated from the crystallographic R-factor (Eq. 129):

$$R = \frac{\sum_i |F_{\mathrm{obs}}| - |k|F_{\mathrm{calc}}|}{\sum_i |F_{\mathrm{obs}}|} \tag{129}$$

Typical R-factors are below 0.2 for a well-refined macromolecular structure.

Beside the atomic coordinates x, y, z, the atomic temperature factor B may be refined at a resolution better than 3.5 Å. This is done in most programs in a separate step where, for example, in program CNS, the target function (Eq. 130)

$$T = E_{\mathrm{XRAY}} + E_R \tag{130}$$

is minimized, where (Eq. 131)

$$\begin{aligned} E_R = &W_B \sum_{(i,j)\text{-bonds}} \frac{(B_i - B_j)^2}{\sigma^2_{\mathrm{bonds}}} \\ &+ W_B \sum_{(i,j,k)\text{-angles}} \frac{(B_i - B_k)^2}{\sigma^2_{\mathrm{angles}} + W_B} \\ &\times \sum_{k\text{-group}} \sum_{j\text{-equivalences}} \sum_{\substack{i\text{-unique} \\ \text{atoms}}} \frac{(B_{ijk} - \overline{B_{ijk}})^2}{\sigma^2_{\mathrm{ncs}}} \end{aligned} \tag{131}$$

The last term is used only if noncrystallographic symmetry restraints should be imposed on the molecules. Normally, isotropic B-factors are applied and refined in macromolecular crystallography only. Even for a high-resolution structure (1.7 Å), the ratio of observations (observed structure factors) to parameters to be

refined (x, y, z, B for each atom) is only about 3. Therefore, as many additional ''observations'' (energy or stereochemistry restraints) as possible are incorporated. In some cases, it is useful to refine the individual occupancy of certain atoms such as bound metal ions or solvent atoms. This must be performed in a separate step.

All of the mentioned refinement procedures are based on the least-squares method. The radius of convergence for this method is not very high because it follows a downhill path to its minimum. If the model is too far away from the correct solution, the minimization may end in a local minimum corresponding to an incorrect structure. Brünger introduced the method of molecular dynamics (MD), which is able to overcome barriers in the *S*-function and find the correct global minimum. MD calculations simulate the dynamic behavior of a system of particles. The basic idea of the MD refinement technique is to increase the temperature sufficiently high for the atoms to overcome energy barriers and then to cool slowly to approach the energy minimum. This MD protocol is designated as simulated annealing (SA). The crystallographic application of the MD or SA technique includes a crystallographic term D, as given in Eq. (126), treated as a pseudoenergy term. A crystallographic MD or SA refinement is capable of overcoming a high-energy barrier occurring in the flipping of a peptide plane. It can be useful in removing model bias from the system.

A new approach is the refinement of macromolecular structures by the maximum likelihood method. Programs working on the basis of this method are REFMAC and CNS. The results derived using the maximum likelihood residual are consistently better than those from least-squares refinement.

If the resolution of a biological macromolecular crystal structure is equal to or better than 1.2 Å, it is in the range of real atomic resolution, and the ratio of observations to parameters is high enough to carry out, in principle, an unrestrained crystallographic refinement. Advances in cryogenic techniques, area detectors, and the use of synchrotron radiation enabled macromolecular data to be collected to atomic resolution for an increasing number of proteins. SHELXL is a program with all tools for the crystallographic refinement of biological macromolecules at real atomic resolution.

Since the advent of structural genomics, automation of all parts of structure analysis has become of paramount importance. A first step in this direction was the compilation of the Arp/Warp program system. This system allows the building and refinement of a protein model automatically and without user intervention, starting from diffraction data extending to a resolution higher than 2.3 Å and reasonable estimates of crystallographic phases. The method is based on an iterative procedure that describes the electron density map as a set of unconnected atoms and then searches for protein-like patterns. Automatic pattern recognition (model building) combined with refinement permits a structural model to be obtained reliably within few CPU hours.

5.3 Accuracy and Verification of Structure Determination

A measure of the quality of a structure determination is the crystallographic *R*-factor given in Eq. (129). For a high-resolution structure, for example 1.6 Å, it should not be much larger than 0.16. As this *R*-factor is an overall number, it does not indicate major local errors. This can be

obtained by the evaluation of a real space *R*-factor, which is calculated on a grid for nonzero elements according to Eq. (132):

$$R_{\text{real space}} = \frac{\sum |\rho_{\text{obs}} - \rho_{\text{calc}}|}{\sum |\rho_{\text{obs}} + \rho_{\text{calc}}|} \qquad (132)$$

where ρ_{obs} is the observed and ρ_{calc} is the calculated electron density.

It has been shown that the conventional *R*-factor may reach rather low values in a crystallographic refinement with structural models that turned out to be wrong later. To overcome this unsatisfactory situation, Brünger proposed the additional calculation of a so-called free *R*-factor. For this purpose, the reflections are divided into a working set (e.g. 90%) and a test set (e.g. 10%). The reflections in the working set are used in the crystallographic refinement. The free *R*-factor is calculated with reflections from the test set, which were not used for the crystallographic refinement and is thus unbiased by the refinement process. There exists a high correlation between the free *R*-factor and the accuracy of the atomic model phases.

The accuracy of the final model expressed by the mean coordinate error can be determined alternatively by a Luzzati or σ_A plot. The mean coordinate error for a macromolecular structure determined with a resolution of 2.0 Å and a crystallographic *R*-factor of 0.2 is in the region of ±0.2 Å.

The stereochemistry of the final model must also be checked. The root-mean-square deviation of bond lengths and bond angles from ideal geometry should not be greater than 0.015 Å and 3.0° respectively. The conformation of the main-chain folding is verified by a Ramachandran plot. The dihedral angles Φ and Ψ are plotted against each other for each residue. The data points should lie in the allowed regions of the plot, which correspond to energetically favorable secondary structures such as α-helices, ß-sheets, and defined turn structures. Exceptions are glycine residues, which may occur at any position in the Ramachandran plot. Further stereochemical parameters to be checked are bond lengths and angles, dihedral angles (e.g. determinating side-chain conformations), noncovalent interactions, geometry of H-bonds, and interactions in the solvent structure. This can be done with the programs PROCHECK or WHAT CHECK.

Nearly all spatial structures of biological macromolecules determined either by X-ray crystallography or nuclear magnetic resonance (NMR) techniques have been and will be deposited with the RCSB Protein Data Bank at Rutgers University. The information of the structural model is in a file that contains for each individual atom of the model a record with atom number, atom name, residue type, residue name, coordinates *x*, *y*, *z*, *B*-value(s), and occupancy. The header records hold useful information such as crystal parameters, amino acid sequence, secondary structure assignments, and references.

6 Applications

6.1 Enzyme Structure and Enzyme–Inhibitor Complex

6.1.1 X-ray Structure of Cystathionine ß-Lyase

Cystathionine ß-lyase (CBL) is a member of the γ-family of pyridoxal-5′-phosphate (PLP)-dependent enzymes that cleaves Cß-S bonds of a broad variety of substrates. The crystal structure of CBL from *Escherichia coli* has been solved using

MIR phases in combination with density modification. The enzyme has been crystallized by the hanging drop vapor diffusion method using either ammonium sulfate or PEG 400 as precipitating agent. The crystals belong to the orthorhombic space group $C222_1$ with unit cell parameters $a = 60.9$ Å, $b = 154.7$ Å, and $c = 152.7$ Å. There is one dimer per asymmetric unit. A native data set has been collected using synchrotron radiation (wavelength 1.1 Å) at the wiggler beamline BW6 at the storage ring DORIS at the Deutsches Elektronensynchrotron (DESY) in Hamburg, Germany. Data sets for three heavy atom derivatives (thiomersalate, 2-mercuri-4-diazobenzoic acid and platinum(II)-2,2′-6,6″-terpyridinium chloride) were registered on an imaging plate scanner (MAR Research, Norderstedt, Germany) using graphite monochromatized Cu Kα radiation from an RU200 rotating anode generator (Rigaku, Tokyo, Japan) operating at 5.4 kW. The reflection data were processed with the MOSFLM package and scaled with programs from the CCP4 program suite. All data sets reveal satisfactory symmetry consistency factors ($R_{\text{merge}} \leq 0.08$) and completenesses (>90%). The heavy atom positions were determined from isomorphous difference Patterson maps using the vector verification routines of program PROTEIN. All derivatives have one common heavy atom–binding site at Cys72, and one of the mercury derivatives shows a second binding site at Cys229. The dimer in the asymmetric unit is related by a local twofold axis that lies parallel to the x-axis. The translation of this local axis was determined from the distribution of the heavy atom sites in the unit cell. An initial MIR map was calculated, followed by solvent flattening, twofold averaging about the local symmetry, and density modification and phase extension to 2.5 Å resolution. Phase calculations, solvent flattening, density modification, and phase extension were done with programs of the CCP4 package. Program AVE was used for the averaging. The quality of the resulting electron density map was sufficiently high to build an almost complete atomic model. Model building was performed on an ESV-30 Graphic system workstation (Evans and Sutherland, Salt Lake City, UT, USA) using program O. The atomic model was refined by energy-restrained crystallographic refinement with XPLOR.

The final model of CBL is made up of two monomers with 391 amino acids each, one cofactor and one hydrogencarbonate molecule per monomer, and 581 solvent water molecules. The final crystallographic R-factor is 0.152 for data from 8.0- to 1.83-Å resolution, and the free R-factor is 0.221. The mean positional error of the atoms as estimated from a Luzzati plot is ±0.19 Å. A homotetramer with 222 symmetry is built up by crystallographic and noncrystallographic symmetry (Fig. 39). Each monomer of CBL (Fig. 40) can be described in terms of three spatially and functionally different domains. The N-terminal domain (residues 1–60) consists of three α-helices and one ß-strand. It contributes to tetramer formation and is part of the active site of the adjacent subunit. The second domain (residues 61–256) harbors PLP and has an α/ß structure with a seven-stranded ß-sheet as the central part. The remaining C-terminal domain (residues 257–395), connected by a long α-helix to the PLP-binding domain, consists of four helices packed on the solvent-accessible side of an antiparallel four-stranded ß-sheet. The fold of the C-terminal and the PLP-binding domain and the location of the active site are similar to aminotransferases. Most

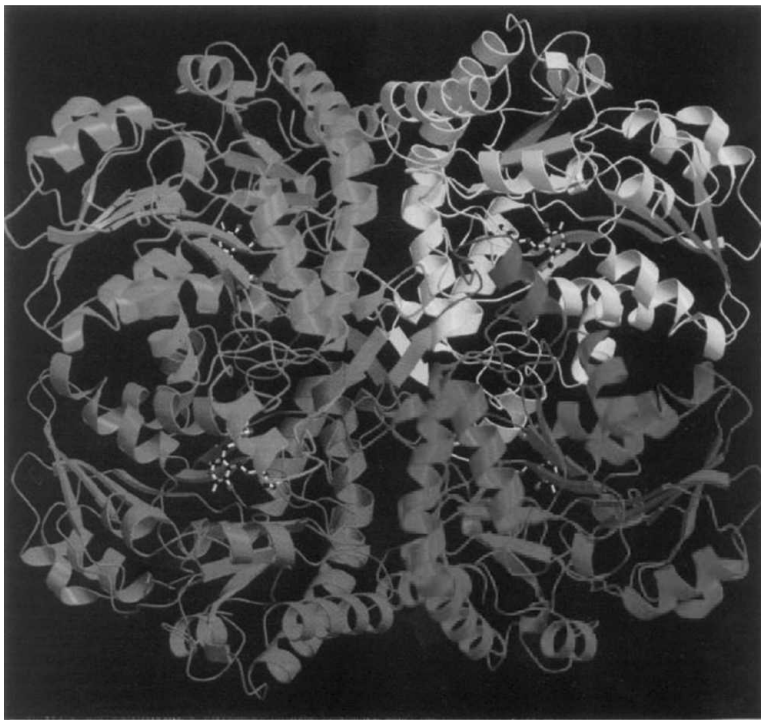

Fig. 39 Ribbon plot of the CBL tetramer viewed along the *x*-axis. The monomers are colored differently. The blue- and green-colored monomers, which are related by a crystallographic axis (horizontal, in the plane of the paper), build up one catalytic active dimer, and the yellow and red ones the other. The location of the PLP-binding site is shown in a ball-and-stick presentation; MOLSCRIPT and RASTER3D. (Reproduced by permission of Academic Press, Ltd., from Clausen, T. et al. (1996) *J. Mol. Biol.* **23**, 202–224.) (See color plate p. xxi).

of the residues in the active site are strongly conserved among the enzymes of the transulfuration pathway. Figure 41 shows the final $2F_{obs} - F_{calc}$ map superimposed with the refined atomic model around the active site of CBL. The cage-like structures for the representation of the electron density correspond to a contour level of 1.2σ. The protein part (main- and side-chain atoms), the PLP cofactor, and the hydrogencarbonate molecule are well defined in the electron density map.

The knowledge of the spatial structure of a given enzyme structure forms the basis for understanding its functional properties. It is now possible to design rational site-directed mutants or determine the structures of enzyme–substrate, enzyme–substrate analog, or enzyme–inhibitor complexes, which will deliver invaluable information in understanding the enzyme's functional properties.

6.1.2 Enzyme–Inhibitor Complex Structures of Cystathione ß-Lyase

The enzyme–inhibitor X-ray structures of ß,ß,ß-tri-fluoroalanine (TFA) and L-aminoethoxyvinylglycine (AVG) with CBL could be determined. In both cases,

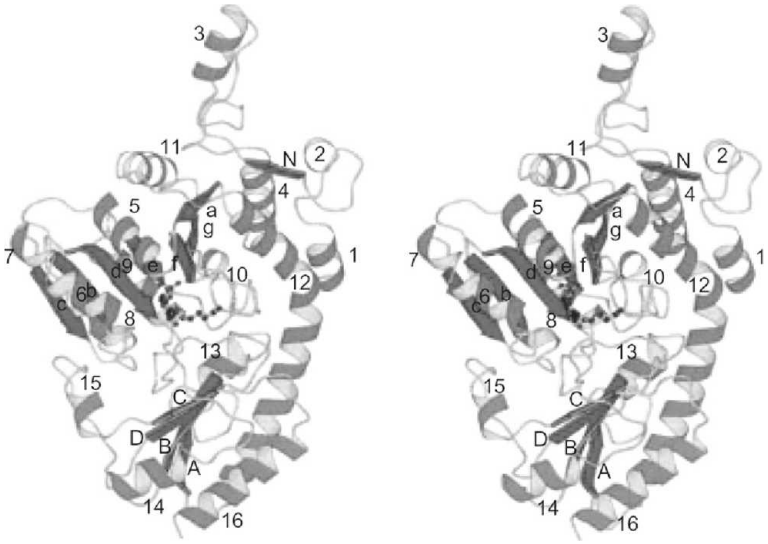

Fig. 40 Stereo ribbon presentation of the CBL monomer, emphasizing secondary structure elements. α-Helices are drawn as green spirals, ß-strands as magenta arrows. PLP and PLP-binding Lys210 are shown in a ball-and-stick representation; MOLSCRIPT and RASTER3D. (Reproduced by permission of Academic Press, Ltd., from Clausen, T. et al. (1996) *J. Mol. Biol.* **23**, 202–224.) (See color plate p. xxiii).

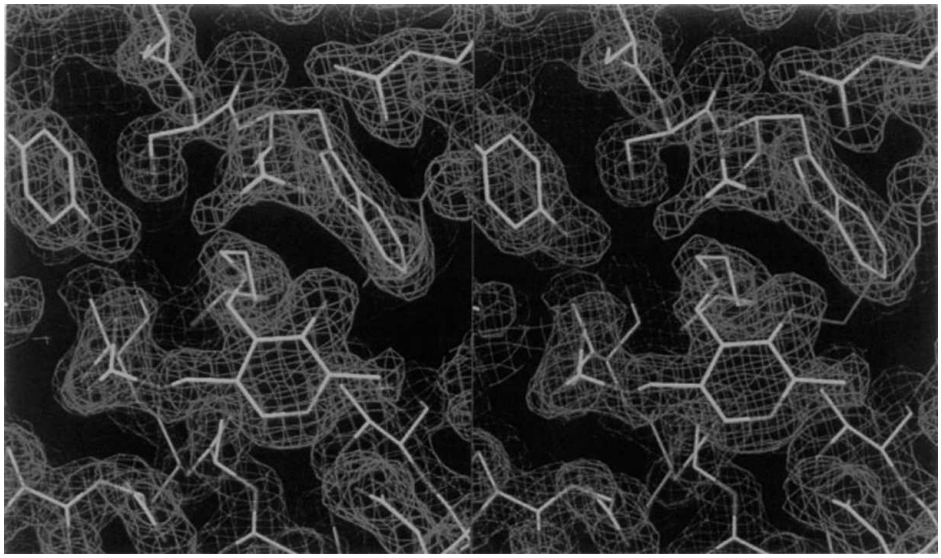

Fig. 41 Stereo plot of the electron density in the active site of CBL, superimposed with the refined model of the region around the cofactor. The $2F_{obs} - F_{calc}$ map is contoured at 1.2σ and calculated at 1.83-Å resolution. (Reproduced by permission of Academic Press, Ltd., from Clausen, T. et al. (1996) *J. Mol. Biol.* **23**, 202–224.)

crystals of the complexes were obtained by incubating the enzyme solution with inhibitor in the millimolar range and subsequent cocrystallization. The resultant crystals were isomorphous with the native enzyme, making it possible to apply the difference Fourier technique in the structure solution. The technical details for the structure analyses are given in the relevant references. The CBL/TFA complex structure was determined to substantiate that the ε-amino group of the active-site Lys210 can react with the nucleophile at the active site via Michael addition, which leads to covalent labeling and inactivation of the enzyme. The final $F_{obs} - F_{calc}$ and $2F_{obs} - F_{calc}$ electron density maps for the CBL/TFA complex around the active site are displayed in Figure 42. Clear, continuous electron density between the cofactor and Lys210 can be seen in this map, indicating a covalent lysine–inactivator–PLP product. In Fig. 42, the blue $F_{obs} - F_{calc}$ map reveals the well-defined electron density for the bound inhibitor. This binding mode of TFA to CBL corresponds to an intermediate in the reaction of TFA with CBL. The structure of the inactivation product proves that Lys210 is the active-site nucleophile reacting via Michael addition with the inactivator. It must also be the residue that transfers a proton from Cα to Sγ in the reaction with the substrates.

The CBL/AVG structure has been determined at 2.2-Å resolution and a crystallographic *R*-factor of 0.164. The X-ray structure shows that AVG binds to the PLP cofactor forming the external aldimine. Lys210 is no longer bound to the PLP cofactor. Figure 43 is an overlay of the atomic models of native CBL(magenta), CBL/TFA (yellow), and CBL/AVG (green). The main difference in inhibitor binding is the location of Cß and its substituents; in the

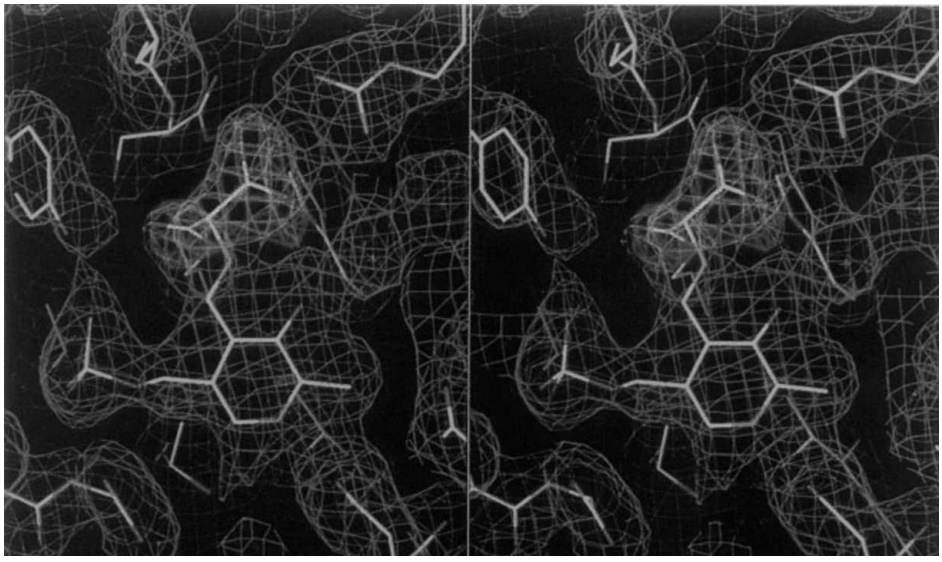

Fig. 42 $F_{obs} - F_{calc}$ (blue) and $2F_{obs} - F_{calc}$ (green) electron density map of the CBL/TFA complex around the active site contoured at 3.5σ and 1.0σ respectively, at 2.3-Å resolution. Fig. 43 Stereo view of a superposition of Tyr111 and the PLP derivative of the unliganded enzyme (magenta), the CBL/AVG adduct (green), and the TFA-inactivated enzyme (yellow); SETOR. (Reproduced by permission of the American Chemical Society, Clausen, T. et al. (1997) *Biochemistry* **36**, 12633–12643.) (See color plate p. xxiv).

TFA complex, the inactivator is directed toward the protein interior (the A face of the cofactor), whereas in CBL/AVG, Cß is located at the B side of the cofactor. The α-carboxylate group in CBL/AVG is located in the same position as the hydrogencarbonate in the native and the α-carboxylate group of TFA in the CBL/TFA complex. The terminal amino group of AVG is held in place mainly by interactions with the hydroxyl group of Tyr111.

The experimental determination of the external aldimine structure in the CBL/AVG complex is of high relevance because it can serve as a rational basis for modeling of substrate and inhibitor binding, leading to more effective herbicides.

6.1.3 **Crystal Structure of the Thrombin–Rhodniin Complex**

This complex structure is an example related to pharmaceutical research. The goal of this special application is the development of more efficient blood anticoagulants. The target enzyme is α-thrombin. This enzyme is a serine proteinase of trypsin-like specificity. α-Thrombin, the key enzyme in hemostasis and thrombosis, exhibits both enzymatic and hormonelike properties, and can be both pro- and anticoagulatory. Rhodniin is a highly specific inhibitor of thrombin isolated from the assassin bug *Rhodnius prolixus*. Such blood-sucking animals have developed various anticlotting mechanisms to prevent local clotting of the victim's blood. These natural thrombin inhibitors are polypeptides of 60 to 120 amino acid residues.

The crystal structure of the noncovalent complex between recombinant rhodniin and bovine a-thrombin has been determined at 2.6-Å resolution. Crystals were obtained by cocrystallization of thrombin with rhodniin in an approximately 1 : 1 molar ratio. The structure could be solved by molecular replacement because the spatial structure of the major constituent, bovine α-thrombin, was known. Only a diffraction

data set of the complex crystal had to be collected. Rotational and translational searches for the orientation and position of the thrombin molecules in the unit cell were performed with the program AMORE. The rotational search showed two solutions with correlation values of 0.22 and 0.20 over 0.09 for the next highest peak. Translational search and rigid body fitting for these two solutions resulted in a correlation value of 0.54, with the two independent complex molecules in the asymmetric unit. The quality of the electron density map calculated from the thrombin phases was good enough in principle to build the model of the rhodniin molecule (noncrystallographic averaging was also applied). The structure was refined with XPLOR to an *R*-factor of 0.189 and a free *R*-factor of 0.262.

Figure 44 shows the structure of the complex between thrombin and rhodniin as a ribbon plot, with α-helices represented as ribbon spirals and ß-strands as arrows. The N-terminal domain binds in a substrate-like manner to the narrow active-site cleft of thrombin. The C-terminal domain, whose distorted reactive-site loop cannot adopt the canonical conformation, docks to the fibrinogen recognition exosite via extensive electrostatic interactions. The peculiarity of this complex structure is that the two KAZAL-type domains of rhodniin bind to two different sites of thrombin.

6.2 Metalloproteins

Metals bound as cofactors in proteins have a great variety of functions. They may be involved in the activation of small inorganic or organic molecules, in oxygen storage and transport, in electron transport, in regulation of biological processes, or in stabilizing a transition state during enzymatic catalysis. Their role may also be solely structural. The chemistry of metals in proteins has attracted the interest of inorganic chemists, and has led to the formation of

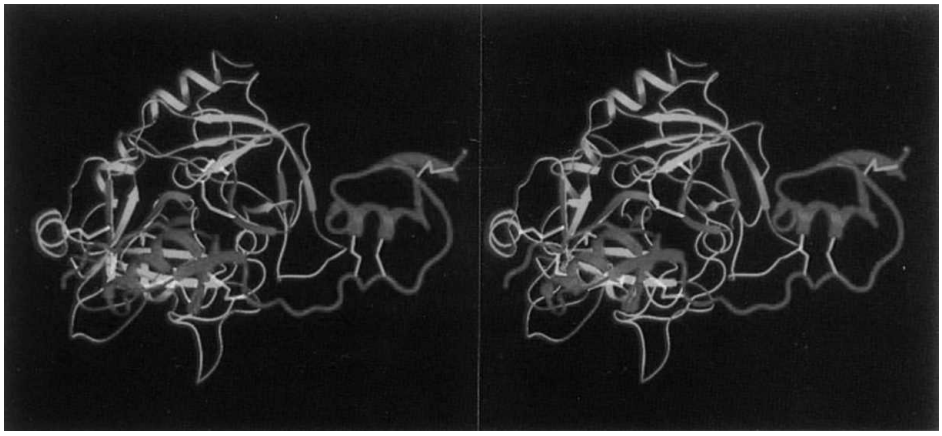

Fig. 44 Stereo view of the complex formed between thrombin (blue) and rhodniin (red) in the thrombin standard orientation, that is, with the active-site cleft facing the viewer and a bound inhibitor chain from left to right. Yellow connections indicate disulfide bridges. Rhodniin interacts through its N-terminal domain in a canonical manner with the active site and through its C-terminal domain with the fibrinogen recognition exosite of thrombin; SETOR. (Reproduced by permission of Oxford University Press, from van de Locht, A. et al. (1995) *EMBO J.* **14**, 5149–5157). (See color plate p. xxiv).

the field of biological inorganic chemistry. As an example of a complex metalloprotein, the multicopper oxidase ascorbate oxidase (AO) is presented.

6.2.1 Crystal Structure of the Multicopper Enzyme Ascorbate Oxidase

The blue protein AO belongs to the group of "blue" oxidases with laccase and ceruloplasmin. These are multicopper enzymes catalyzing the four-electron reduction of molecular oxygen with concomitant one-electron oxidation of the substrate. The crystal structure of AO has been solved by the MIR technique and refined to 1.9-Å resolution. The peculiarity of this structure determination is briefly described. It consists in the utilization of the information of two different crystal forms. In both crystal forms, the molecules arrange themselves as homotetramers with 222 symmetry, but in crystal form 1, one of these twofold axes is realized by a crystallographic twofold axis resulting in two subunits per asymmetric unit. In crystal form 2, one homotetramer is found per asymmetric unit. In crystal form 1, six isomorphous heavy atom derivatives could be found and interpreted. An initial MIR map was calculated, solvent flattened, and averaged about the local twofold axis. For crystal form 2, no phase information was available. From the averaged uninterpreted MIR map, a whole tetramer was selected and used for rotational and translational searches in crystal form 2. This was successful and provided the necessary phase information for crystal form 2 and, additionally, the local symmetry. Now, averaging could be performed both separately in the two crystal forms and subsequently between both crystal forms. The averaged electron density was transported into both unit cells and a new macrocycle of averaging could be started. These macrocycles were used to extend the phases from 3.5 Å to the full attainable resolution. This structure analysis was the first example where a molecular replacement was carried out with an uninterpreted MIR electron density–based model.

AO is a homodimeric enzyme with a molecular mass of 70 kDa and 552 amino acid residues per subunit (zucchini). The three-domain structure and the location of the mononuclear centers and trinuclear copper centers in the AO monomer as derived from the crystal structure are shown in Fig. 45. The folding of all three domains is of a similar ß-barrel type. The mononuclear copper site is located in domain 3 and the trinuclear copper species is bound between domains 1 and 3. The coordination of the mononuclear copper site is depicted in Fig. 46. It has the four canonical type-1 copper ligands (His, Cys, His, Met), also found in plastocyanin and azurin. The copper is coordinated to the ND1 atoms of His445 and His512, the SG atom of the Cys507, and the SD atom of Met517 in a distorted trigonal geometry. This unusual coordination geometry confers this copper site with its blue color. The trinuclear copper site (see Fig. 47) has eight histidine ligands symmetrically supplied by domains 1 and 3 and two oxygen ligands. The trinuclear copper site may be divided into a pair of copper (CU2, CU3), with six histidine ligands in a trigonal prismatic arrangement. The pair is bridged by an OH^-, which leads to a strong antiferromagnetic coupling and makes this copper pair electron paramagnetic resonance silent. The remaining copper has two histidine ligands and an OH^- or H_2O ligand. A binding pocket for the reducing substrate, which is complementary to an ascorbate molecule, is located near the mononuclear copper site and is accessible

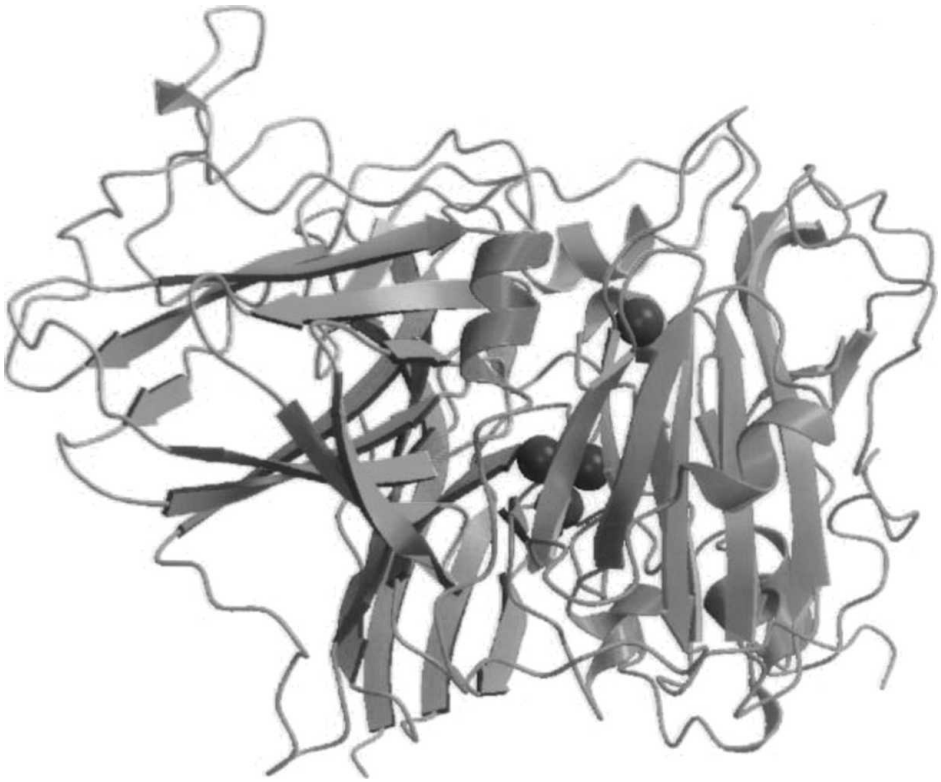

Fig. 45 Schematic representation of the monomer structure of AO. (Reproduced by permission of World Scientific Publishing Co., from Messerschmidt, A. (1997) Spatial Structures of Ascorbate Oxidase, Laccase and Related Proteins, in: Messerschmidt, A. (Ed.) *Multi Copper Oxidases*, World Scientific Publishing, Singapore.)

from solvent. A broad channel providing access from the solvent to the trinuclear copper species, which is the binding and reaction site for the dioxygen, is present in AO. During catalysis, an intramolecular electron transfer between the mononuclear copper site and the trinuclear copper cluster occurs. The distances between the mononuclear copper and the three coppers of the trinuclear center are 12.20, 12.69, and 14.87 Å, respectively. Furthermore, the crystal structures of functional derivatives of AO such as the reduced, azide, and peroxide form have been determined. They show considerable changes at the trinuclear copper site in the reduced form and the peroxide or azide binding to the trinuclear copper species in the relevant structures. The X-ray studies on AO delivered essential information in understanding the catalytic mechanism.

6.2.2 Crystal Structure of Cytochrome-*c* Nitrite Reductase Determined by Multiwavelength Anomalous Diffraction Phasing

The spatial structure of cytochrome-*c* nitrite reductase from *Sulfurospirillum deleyianum* has been solved by the MAD technique using synchrotron radiation and

refined at a resolution of 1.9 Å to a *R*-factor of 0.18. The data collection for the MAD phasing was performed at the wiggler beamline BW6 at the storage ring DORIS at DESY in Hamburg, Germany. At the beginning, an X-ray fluorescence spectrum around the Fe K absorption edge was registered using an NaI(Tl) scintillation counter. Evaluation of the spectrum with program DISCO gave the anomalous dispersion contributions, f' and f'', as a function of photon energy (Fig. 48). Subsequently, diffraction data were collected at three different photon energies. Two of them, 7141 and 7129 eV, correspond to maximum f'' and minimum f' respectively. A third high-resolution data set (1.90 Å resolution) was collected at a photon energy of 11 808 eV. All data sets were obtained from a single crystal that had been shock-frozen at 100 K. Anomalous difference Patterson maps were calculated from the data collected at f'' maximum of the Fe K absorption edge. Correlated peaks that appeared in all three Harker sections were chosen and used for phasing with MLPHARE. The highest peaks from the resulting Fourier map were analyzed for consistency with the anomalous difference Patterson map and, if correct, used for a new cycle of phase calculations. Thus, it was possible successively to find 15 iron positions, which divided into three groups of five. Phasing with program SHARP produced an interpretable electron density map, which was solvent flattened and threefold averaged with program AVE. The resulting electron density map at a resolution of 1.9 Å was of high quality and allowed the construction of the complete atomic model into that map.

Cytochrome-*c* nitrite reductase (58 kDa) catalyzes the six-electron reduction of nitrite to ammonia as one of the key steps in the biological nitrogen cycle, where it participates in the anaerobic energy metabolism of dissimilatory nitrate ammonification. The crystal structure shows that the enzyme is a homodimer

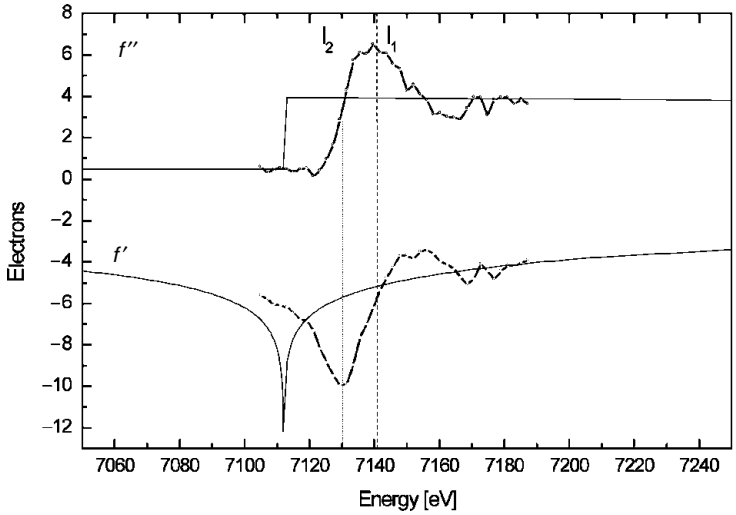

Fig. 48 Dispersion terms as a function of the photon energy as obtained from an X-ray fluorescence scan from cytochrome-*c* nitrite reductase sample crystal and evaluation with DISCO.

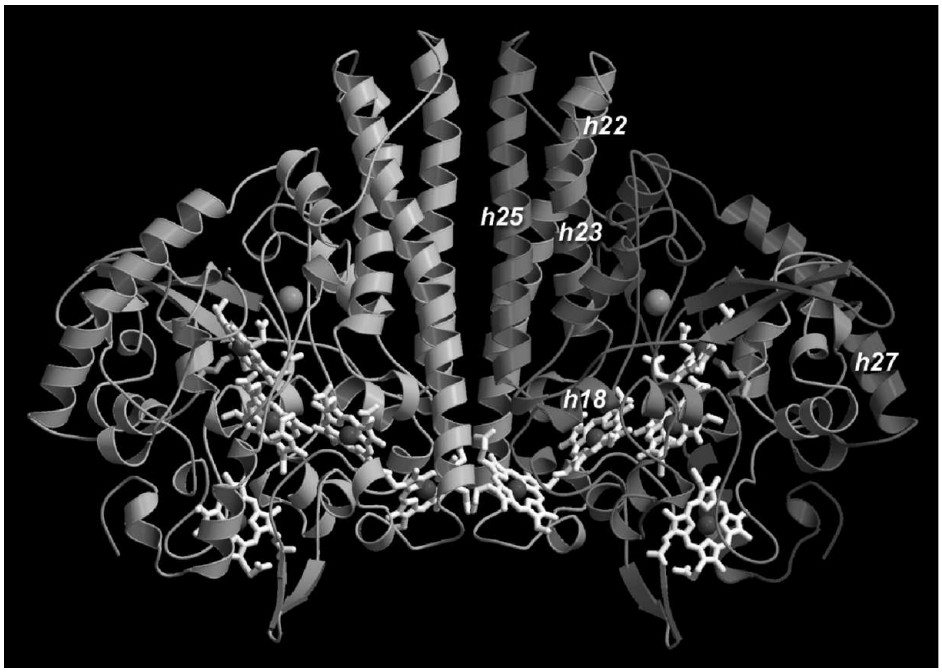

Fig. 49 Overall structure of the nitrite reductase dimer. A front view with the dimer axis oriented vertically, five hemes in each monomer (white), the Ca^{2+} ions (grey), and Lys133 that coordinates the active-site iron (yellow). The dimer interface is dominated by three long α-helices per monomer. All hemes in the dimer are covalently attached to the protein. (Reproduced by permission of Macmillan Magazines, Ltd., from Einsle, O. et al. (1999) *Nature* (*London*) **400**, 476–480.) (See color plate p. xxii).

of ~100 Å × 80 Å × 50 Å, with 10 hemes in a remarkably close packing (Fig. 49). The protein folds into one compact domain with α-helices as the predominant secondary structural motif, ranging from short helical turns to four long helices at the C-terminal end of the peptide chain (Fig. 49). There are eight 3_{10} helices three- or four-residues long, seven of which occur within the first 200 residues, ß-sheet structures are found only in two short, antiparallel strands, where one is part of a funnel-like cavity leading to the active site. Dimer formation is mediated by helices *h*22 and *h*25, with helix *h*25 as the key element, as it interacts with its counterpart in the other monomer over its full length of 28 residues, corresponding to 42 Å. The five hemes in the monomer of cytochrome-*c* nitrite reductase are in close contact, with Fe-Fe distances of between 9 and 12.8 Å. They are arranged as a group of three, almost coplanar, hemes, with heme 1 forming the active site. Hemes 2 and 5 are farther apart and are not coplanar with hemes 1, 3, and 4. All hemes except heme 1 are bis-histidynyl-coordinated, and are linked to the peptide backbone by thioether bonds to the cysteine residues of a classical heme-binding motif for periplasmic proteins, Cys-X_1-X_2-Cys-His. The propionate side chains of heme 1 form part of the active-site cavity. The site of nitrite reduction is clearly heme

1, with NZ atom of Lys133, replacing a histidine in the classical binding motif, and an oxygen atom of a sulfate ion, present in the crystallization buffer. An additional electron density maximum detected close to the active site was assigned to Ca^{2+}.

S. deleyianum cytochrome-*c* nitrite reductase reduces not only nitrite to ammonia but also the potential intermediates NO and hydroxylamine. No intermediates are released during nitrite turnover. Obviously, the active site accomodates anions and uncharged molecules and releases the ammonium cation only after full six-electron reduction. The preference for anions is reflected by a positive electrostatic potential around and inside the active-site cavity. The cationic product might make use of a second channel leading to the protein surface opposite to the entry channel. It branches before reaching the protein surface and ends with both arms in areas possessing a significant electrostatic surface potential. The existence of separate pathways for substrate and product with matched electrostatic potential could also contribute to the enzyme's high specific activity compared to the siroheme-containing reductases that catalyze the same reaction.

6.3 Large Molecular Assembly

6.3.1 Crystal Structure of 20S Proteasome from Yeast

The controlled degradation of proteins in the interior of cells is of central significance for many processes that range from cell cycle control and differentiation to cellular immune response. The target protein is labeled for destruction by the covalent linkage of a small protein called *ubiquitin* and is degraded after adenosine triphosphate (ATP)-driven unfolding in the closed internal chamber of a large protein complex, which is known as *26S proteasome* (molecular mass 2 000 000 Da). The core and the proteolytic chamber of the 26S proteasome are formed by the catalytic 20S particle (molecular mass 700 000 Da). This particle is flanked at each end by a so-called 19S cap, which seems to be responsible for the recognition and unfolding of the ubiquitin-labeled target proteins. The eukaryotic catalytic 20S machinery consists of 14 different but related protein subunits that assemble to the overall structure of 28 protein chains, a monster of the molecular world. The structure of the 20S proteasome from *Saccharomyces cerevisiae* has been elucidated at atomic resolution. This is one of the most complex structures that has been determined up to now, excluding symmetrical systems such as viral capsids. It shows that complexity itself is no limit to understanding a structure on the atomic level.

The structure analysis is briefly outlined. Crystals could be obtained by the hanging drop vapor diffusion method with a final precipitant concentration of 12% MPD in the drop (pH 6.5). The crystals are monoclinic, space group $P2_1$, cell parameters $a = 135.7$ Å, $b = 301.8$ Å, $c = 144.7$ Å, and ß $= 112.6^\circ$, and have one 20S particle per asymmetric unit. Data sets with two different inhibitors were collected at the wiggler beamline BW6 at DESY with radiation of $\lambda = 1.1$ Å and at 90 K temperature. The mean attainable resolution was 2.4 Å. A self-rotation function calculated at 5-Å resolution revealed the orientation of the local twofold axis. The atomic model of the 20S proteasome from *Thermoplasma acidophilum* could be used for molecular replacement calculations (program AMORE) at 3.5-Å resolution, and a prominent solution could be found. The resultant electron density map was cyclically averaged about the local

twofold axis. The individual subunits were identified according to their characteristic amino acid sequences and were built into the map. The final model with the lactacystin inhibitor was refined at a resolution of 2.4 Å to an *R*-factor of 0.26, consisting of 48 888 proteins, 30 inhibitors, 18 magnesium atoms, and 1800 solvent molecules.

The structure of the eukaryotic proteasome is important because it is much more complex than its archaebacterial relative, which has two types of subunits, α and ß, only. The α-subunits do not seem to be catalytic but they may self-assemble to form sevenfold rings. In contrast, the ß-subunits show catalytic activity but are not able to assemble themselves. The two components assemble themselves to a stack of four rings, two outer α-rings, which enclose an inner pair of ß-rings. The eukaryotic proteasome retains the important property, however, that the single subunits of the sevenfold rings are different, probably reflecting the increased biological functions. The exact sevenfold symmetry of the particle is lost and a twofold symmetry remains solely to give seven different α- and seven different ß-subunits (Fig. 50a and b). In the proteasome, the unfolded protein is cut

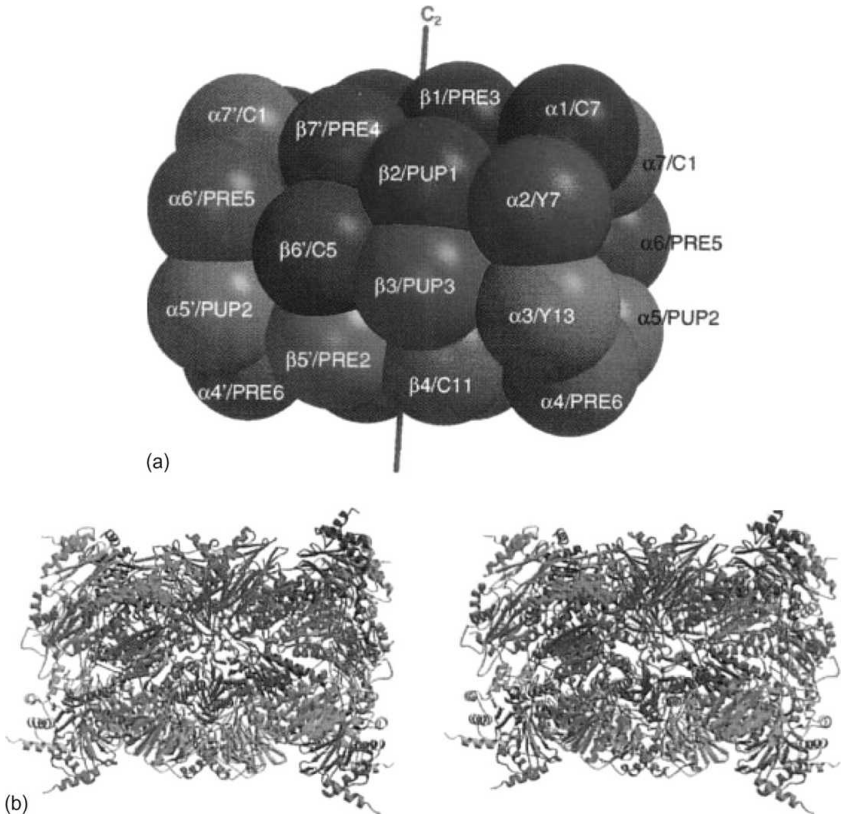

Fig. 50 Topology of the 28 subunits of the yeast 20S proteasome drawn as (a) spheres and (b) ribbon representation; MOLSCRIPT, RASTER3D. (Reproduced by permission of Macmillan Magazines Ltd., from Groll, M. et al. (1997) *Nature (London)*, **386**, 463–471.)

into peptide products in the inner chamber of the 20S particle, and these have a length distribution with a center around octa- or nonapeptides. These sizes are appropriate to bind to MHC-class-I molecules.

Keywords

BAC
Bacterial artificial chromosome. A single copy cloning vector for large DNA fragments (on the order of 100 to 200 kbp).

Contig
A segment of contiguous sequence, uninterrupted by gaps, assembled from a number of overlapping sequence reads.

Cytogenetic Form
Subspecies of *Anopheles gambiae*, as classified by paracentric chromosomal inversions.

DDT
The pesticide dichlorodiphenyltrichloroethane.

Mate Pair
The two sequence reads derived from either end of a DNA fragment.

Orthologs
Genes in different species arising from a single ancestral gene (e.g. human α-globin and mouse α-globin).

Paralogs
Genes in the same species, arising from local gene duplication (e.g. human α-globin and human β-globin).

PEST
The pink eye standard laboratory strain of *Anopheles gambiae*.

Read
A DNA sequence, approximately 500 bp in length, that is derived from a template DNA molecule. The terms ''read,'' ''trace,'' ''lane,'' and ''electropherogram'' are often used interchangeably.

SNP
Single nucleotide polymorphism.

Scaffold
A set of contigs separated by sequence gaps but of defined order and orientation.

Vector
An organism that carries disease-causing pathogens from one host to another.

WHO
World Health Organization.

Shotgun
A method of whole-genome sequencing where high molecular weight DNA from an organism is randomly fragmented and sequence reads are obtained from fragment ends. Sequencing is done at some level of redundancy (coverage) such that each nucleotide in the genome is represented in multiple reads. The consensus genome sequence is reconstructed computationally on the basis of overlaps among sequence reads.

Sporogeny
The stages of the *Plasmodium* development cycle that take place within the mosquito vector.

Mosquito-borne illnesses exact an enormous toll on human health; malaria parasites alone currently infect approximately 500 million people, more than 1 million of whom will die this year. *A. gambiae* is the principal malaria vector in sub-Saharan Africa, where 90% of the world's deaths due to malaria occur. Historically, the greatest successes in prevention of malaria, yellow fever, and other mosquito-borne disease have come from controlling the mosquito vector. Current work on vector control holds much promise and can be addressed more efficiently by genomic approaches. The reference genome sequence of *A. gambiae sensu stricto* (a representative member of the cryptic *A. gambiae* species complex) has yielded novel insecticide targets, has facilitated the identification of genes involved in insecticide resistance, and has led to the identification of genes that underlie the strong preference of this vector for human blood. Germ-line transformation of the mosquito has been achieved and the reference genome sequence will facilitate efforts to develop a tractable genetic control strategy for mosquitoes. The publication of the *A. gambiae* genome is a landmark in medical entomology, both because this was the first vector genome to be fully sequenced and because of the impact of this mosquito on public health.

1 The Mosquito and Infectious Disease

1.1 Scope and Impact of Mosquito-borne Disease

Mosquitoes, which are members of the insect family Culicidae of the order Diptera, the flies, are medically the most important group of arthropod vectors, or transmitters, of human pathogens. Mosquitoes transmit a large number of human viral pathogens, including the viruses that cause dengue, yellow fever, and West Nile encephalitis, as well as several nematodes species that cause

lymphatic filariasis. But, by far, the most important mosquito-borne disease is malaria, which is caused by protozoan parasites of the genus *Plasmodium*. Malaria shares with HIV/AIDS and tuberculosis the distinction of being one of the three most important disease-specific causes of human mortality in the world today. Estimates of the public health impact of malaria are imprecise, but it is widely assumed that approximately half a billion people are currently infected with malaria parasites and that more than 1 million die each year, principally infants and very young children. Although four different *Plasmodium* species infect humans, nearly all of the mortality is caused by the parasite *Plasmodium falciparum*.

1.2 Strategies for Malaria Control

The etiologic agent of human malaria and the pathogen's mode of transmission by mosquitoes were both determined in the latter years of the nineteenth century by Charles Laveran (who discovered the parasite) and Ronald Ross and Battista Grassi (they independently identified the vector), but malaria has been recognized as an important human disease for centuries. By the fifth century, Hippocrates had clearly described the clinical symptoms associated with three different species of malaria parasites, and it was widely recognized in those times that the disease was caused by association with marshy environments with bad air (thus the name malaria).

Antimalarial drugs and interventions targeted at the vector remain the primary public health measures for dealing with malaria. Two very important discoveries emerged during World War II: the antimalarial drug chloroquine, and the insecticide DDT (dichlorodiphenyltrichloroethane). Both were extremely effective, very inexpensive to produce, unencumbered by patents, and had remarkably low levels of toxicity. (The adverse environmental impacts of DDT, which is a highly stable molecule that can accumulate to toxic levels in species at or near the top of the food chain, were entirely due to its widespread use for control of insects of agricultural importance.) In the decades of the 1950s and 1960s, chloroquine and DDT (and related types of antimalarials and insecticides) formed the basis for very effective, countrywide malaria-control programs that were implemented in the framework of a World Health Organization-directed worldwide Malaria Eradication Campaign. Malaria was permanently eradicated from most developed countries in the temperate-climate regions of the world and prevalence was significantly reduced in many other malaria-endemic countries. Unfortunately, worldwide eradication was an impossible goal, and by the 1970s, the responsibility for managing and funding malaria-control programs was returned to national health programs and budgets.

Several important lessons emerged from the WHO (World Health Organization) Malaria Eradication Campaign. Vector control using insecticides like DDT sprayed on the walls of houses was an extremely effective malaria-control strategy. However, it was costly and required well-managed teams of technically skilled people. Moreover, it was effective only in countries with sufficient infrastructures like roads and bridges for vector-control teams to reach the population that was at risk. Control programs based exclusively on antimalarial drugs like chloroquine

were even more costly because of the requirement for active case detection. But as active control programs lapsed, effective and inexpensive antimalarial drugs like chloroquine found their way into malaria-endemic communities through either the national primary health systems or through the marketplace.

For most of sub-Saharan Africa, with the notable exceptions of some of the countries in southern Africa and around some of the major cities, the organized malaria-control programs developed during the WHO Malaria Eradication Campaign were not even attempted, particularly in rural areas. Nonetheless, inexpensive antimalarial drugs like chloroquine became widely available, even in relatively remote rural communities in most of Africa. Unfortunately, chloroquine-resistant *P. falciparum* appeared in coastal Kenya in 1978, and in the subsequent two decades, resistant parasites became the prevalent form almost throughout sub-Saharan Africa. Although the health impact of the publicly available and affordable antimalarials like chloroquine was never assessed, the emergence of parasite resistance to this drug has been coincident with an equally poorly documented perception that malaria-specific mortality in Africa has been increasing. Today, chloroquine is an effective antimalarial only in parts of west Africa, and unfortunately, replacement drugs like Fansidar (sulfadoxine/pyramethamine), mefloquine, and – more recently – artemisinin-based drugs (based on the ingredients in *Artemisia annua*) are either very costly or are themselves provoking the emergence of resistant parasite strains. As resistance to existing antimalarial drugs becomes more entrenched, there is increased need for novel and effective vector-control strategies.

2
A. gambiae, the Principal Vector of Malaria

2.1
The Mosquito and the Malaria Parasite

Malaria parasites are intracellular human parasites that undergo cycles of invasion, growth, and mitotic replication in erythrocytes. The parasites are transmitted among human hosts by *Anopheles* mosquitoes, which ingest parasites when they feed on the blood of an infected human host. The malaria parasites undergo a complex developmental cycle, referred to as the *sporogenic developmental cycle*, in the mosquito vector. A small fraction of the *Plasmodium*-infected erythrocytes are differentiated forms called *gametocytes* that are triggered by hypoxanthine in the mosquito's midgut to develop into male and female gametes. These fuse to form diploid zygotes (the only diploid stage in the *Plasmodium* life cycle), which traverse the mosquito's midgut cells and then undergo a meiotic division and differentiate further into growth stages called the *oocysts*. After approximately one week of growth and mitotic divisions, a single oocyst will produce several thousand specialized, haploid forms called *sporozoites*. On maturation of the oocysts, the sporozoites are released into the mosquito's open circulatory system through which they are transported passively to the salivary glands. These parasite stages invade the salivary gland cells and accumulate in the salivary ducts and acini of these cells, from where they are injected into a host capillary when the mosquito next takes a blood meal. In the human host, the sporozoites are transferred passively through the circulatory system to the liver, where they invade hepatocytes. In these cells, the parasite undergoes approximately a

dozen rounds of mitotic replication that result in the production of several thousand *merozoites*. On completion of this cycle of replication, the infected hepatocytes rupture and release the merozoites into the circulatory system, where they invade erythrocytes and initiate the blood cell cycle of infection that causes disease.

Plasmodium falciparum malaria is widely distributed throughout the widely distributed throughout the world, especially in tropical regions bounded by approximately 30° north and south latitude. Over this broad distribution, parasite prevalence in human populations with endemic *P. falciparum* ranges from low levels of a few percent to peak endemicity levels, approaching 100% in rainy seasons when transmission is maximum. Of the approximately 500 or more *Anopheles* species found worldwide, several dozen are involved in the transmission of malaria parasites. The *Anopheles* vectors are the major determinant of local levels of disease endemicity. The majority of *Anopheles* species are probably physiologically competent to support sporogonic development of the parasite. In order for malaria parasites to remain endemic in a particular human community, the vector population must effectively propagate each infected human case to – on average – more than one new human host. With an effective case reproductive rate of less than 1, the parasite cannot be stably maintained in a human population.

Four important features of mosquito biology determine whether a particular *Anopheles* species will be effective as a malaria vector: (1) It must be a physiologically suitable host. (2) It must also be a moderately abundant species in order to maintain a density sufficient to achieve transmission. (3) The mosquito must also take blood meals from people. Because the vector must both acquire the infection in one blood meal and then take a second meal on another human host after the sporogonic cycle is complete, blood-meal host choice is an important determinant of vectorial effectiveness. (4) Finally, and most important, the age structure of the vector population must be such that a sufficient portion survives long enough to allow sporogonic development to be completed.

2.2 *A. gambiae* is a Polymorphic Species

Approximately 90% of the world's malaria-specific mortality occurs in sub-Saharan Africa, where the primary vector is *A. gambiae*. A second important African vector is the mosquito *Anopheles arabiensis*, which is a close relative of *A. gambiae* in a cluster of seven related African species known as the *A. gambiae sibling-species complex*. This extraordinary concentration of malaria in Africa is largely a consequence of the close ecological association of *A. gambiae* and *A. arabiensis* with people. *A. gambiae*, in particular, takes blood meals almost exclusively from people; its larval stages develop in temporary pools of water, like tire ruts, animal hoof-prints, and irrigated agricultural fields that are produced by human activity; and when not laying eggs or mating, the adult females spend most of their time in human dwellings either blood feeding or resting while eggs develop.

Perhaps, because of the close association this mosquito has with people, it is also a highly polymorphic species. Like a number of other insects, especially in the order Diptera, *A. gambiae* and its sibling species have giant polytene chromosomes in many of their tissues, and these have facilitated population analysis. During the

past three decades, careful studies of the polytene chromosomes of field-collected *A. gambiae* from countries in west Africa have revealed patterns of distribution of a number of paracentric chromosome inversions that suggest the presence of at least five different reproductively isolated chromosome forms designated as Bissau, Bamako, Mopti, Forest, and Savanna. (All *Anopheles* genomes are based on three pairs of chromosomes, two autosomes, and an X and Y sex-determining pair, and in most *Anopheles* species, cells of either the larval salivary glands or nurse cells of developing ovaries contain polytene chromosomes that, when properly prepared, will show a reproducible, species-specific banding pattern. In addition to their value in species identification and population studies, polytene chromosomes are excellent for physical mapping of cloned DNA.) Most of the inversions that distinguish chromosomal forms are restricted to the right arm of chromosome 2. In geographic regions where two or more of the chromosome forms are present, inversion heterozygotes expected from interbreeding of forms are either totally absent or are present at levels significantly below Hardy–Weinberg expectations. Three of these forms, Bamako, Mopti, and Savanna, have been carefully studied in Mali, where they exhibit clear differences in ecology. In spite of considerable effort by several groups to identify molecular markers diagnostic of these chromosome forms, the only molecule found thus far that distinguishes different *A. gambiae* populations is the rDNA, where sequences in both the IGS and ITS regions can be used to identify what are referred to as *S and M ribosomal DNA* (rDNA) *types*. In Mali, the M rDNA type is associated exclusively with Mopti cytogenetic specimens and the S rDNA type is found only in Savanna and Bamako specimens. In other parts of west Africa, however, the association between karyotype and rDNA type is less predictable. Both S and M rDNA types are found in Forest, Bissau, and Savanna cytogenetic forms.

The frequencies of polymorphic paracentric inversions are clearly important characters in *A. gambiae* as well as in its sibling species, *A. arabiensis*. In both species, inversion frequencies have been shown to vary along clines associated with climatic and ecological parameters, and the data from Mali, supporting the presence of chromosomally distinct *A. gambiae* forms that are both ecologically and genetically differentiated is quite robust. Unfortunately, karyotyping of wild specimens is both difficult and possibly biased, and the lack of congruence between the chromosomal inversion and rDNA molecular markers means that the population structure of this important African vector remains unclear.

3 The *A. gambiae* Genome

3.1 The PEST Strain

The *A. gambiae* PEST (Pink Eye STandard) strain was chosen for genome sequencing because it had a fixed chromosomal arrangement, a sex-linked pink-eye mutation that can readily be used as an indicator of cross-colony contamination, and because clones from two different PEST-strain BAC (Bacterial Artificial Chromosome) libraries had already been end sequenced and physically mapped. The pink-eye mutation originated in a colony called *A. gambiae LPE*, established in 1951

at the London School of Hygiene and Tropical Medicine from mosquitoes collected in Lagos, Nigeria. In 1986, this mutation was introduced into a colony of *A. gambiae* from western Kenya by crossing males of the LPE strain with female offspring of wild caught Kenyan *A. gambiae* (the Savanna form), selecting males from the F2 of this cross and then crossing them again with additional female offspring of wild caught Kenyan *A. gambiae*. From the F2 offspring of this second outcross to Kenyan mosquitoes, a strain was selected that was fixed for pink eye. This outcrossing scheme was repeated once more in 1987, producing a pink-eye strain with a genetic composition largely constituted of the western Kenya Savanna cytogenetic form. In each of these crosses, several hundred female offspring of at least 20 wild caught mosquitoes were used in the cross. This strain, designated *A. gambiae PE*, was polymorphic for the inversions 2La (32%) and 2Rbc (19%). The 2Rbc inversion is characteristic of Mopti, indicating that the original LPE strain from Nigeria was the Mopti form. This inversion was apparently balanced by the uninverted form because no 2Rbc/bc individuals were detected in the colony. From this PE strain, Mukabayire and Besansky selected a set of nine families whose female parent and at least 20 female offspring were fixed for the standard chromosome karyotype. The progeny of these nine families were pooled to form the *A. gambiae* PEST strain. This strain may clearly have some Mopti-derived DNA as the standard karyotype is shared by Mopti and Savanna and the original PE strain did have the 2Rbc inversion rather than the 2Rb that is typical of Savanna. When tested, this colony was fully susceptible to *P. falciparum* from western Kenya.

3.2 The Draft Genome Sequence

Obtaining the draft genome sequence of *A. gambiae* was a collaborative effort, with sequence data provided by Celera, The Institute for Genomics Research, and the French National Sequencing Centre, Genoscope. The whole-genome shotgun method was adopted for this project, given its speed and efficiency and in consideration of its previously successful use for the *Drosophila* genome project. Paired end reads were derived from 2 254 546 plasmid clones with 2-, 10-, or 50-kb inserts, (50 kbp plasmid libraries had the bulk of their insert sequence excised during the initial steps of library construction, and only the insert ends were propagated in *Escherichia coli*.) and approximately 40 000 large-insert BAC clones, to give a total of 10.2-fold sequence coverage of the genome, estimated from CoT analysis to be about 260 Mbp. All plasmid and BAC libraries were constructed using DNA extracted from several hundred adult PEST-strain mosquitoes. Libraries from male and female mosquitoes were constructed separately and sequenced in equal proportion, giving approximately equal coverage of the autosomes and accordingly less coverage of the X and Y chromosomes. All electropherograms are downloadable from the NCBI trace archive (http://www.ncbi.nlm.nih.gov/Traces/trace.cgi?) or Ensembl trace server (http://trace.ensembl.org).

The WGS data set was assembled using Celera's assembly software, where algorithms are executed in a stepwise manner. An initial Blastn comparison of each sequence read to every other sequence read is used to detect overlaps (the overlap criteria being 40 or more base pairs with 6% or less mismatch). Reads within each

cluster of overlapping sequences are then assembled into a contiguous consensus sequence (contig). Contigs that appear from read depth to be single copy in the genome are ordered and oriented into longer scaffolds, using mate pairs (two sequence reads derived from either end of a clone insert). Mate pairs are also used to guide computational intrascaffold gap filling, whereby one mate is located in the sequence flanking either side of a gap and its partner is placed within the gap. The resulting assembly is thus a set of typically very long scaffolds that are ordered and oriented sets of contigs whose intervening gaps are of known mean length and whose standard deviations are based on estimated library insert sizes.

The published draft of the *A. gambiae* whole-genome assembly was comprised of 8987 scaffolds, spanning 278 million base pairs (Mbp) of sequence. It is important to note that a small number of very large scaffolds cover most of the genome (91% of the sequence is represented by 303 scaffolds greater than 30 kb), and that many small scaffolds are expected to fit within intrascaffold gaps. In the entire assembly, there are 8986 gaps between scaffolds and 9964 gaps within scaffolds. Gaps within scaffolds are largely due to repetitive sequences that could not be uniquely placed on the basis of sequence overlap or mate-pair information and may also occasionally be due to a simple lack of coverage. Genbank accession numbers for the 8987 genome scaffolds are AAAB01000001 through AAAB01008987 and the scaffold sequences are downloadable as a set from ftp://ftp.ncbi.nih.gov/genbank/genomes/*Anopheles*_gambiae/Assembly_scaffolds.

While use of the whole-genome shotgun approach for this project was well justified by time and cost savings, it is important to understand that the present form of the assembly is that of a draft genome sequence and, as with all draft genomes, there are numerous gaps that will require focused finishing efforts. Further, because of the fact that the plasmid libraries were derived from whole adult mosquitoes, some contaminating sequence from commensal gut bacteria was expected and were in fact observed. Scaffolds with hits to bacteria were flagged in their Genbank record as containing putative contaminating sequence of possible bacterial origin. In total, 213 short scaffolds were flagged, which together comprised 36.5 kb or 0.013% of the genome. These scaffolds were not culled from the assembly because of the remote possibility that some may represent real horizontal transfer events.

3.3 Genome Assembly, Genome size, and Physical Mapping

The sum of all the assembled *Anopheles* genome scaffolds is 278 Mb, which is significantly larger than the genome size of 260 Mb predicted by CoT analysis. There are several reasons why the assembly is close to, but slightly larger than the genome size predicted by CoT analysis. First, many small scaffolds may fit into gaps within other larger scaffolds. Second, because the X chromosome accounts for close to 20% of the genome but is underrepresented in males relative to the autosomes, CoT analysis using a mixed-sex pool of mosquitoes is expected to underestimate genome size. The third likely cause of discrepancy is the unanticipated assembly of highly variant alleles into separate contigs, as discussed further below (Sect. 3.4 Genetic variation).

The final step in defining the reference genome for *A. gambiae* was to order and

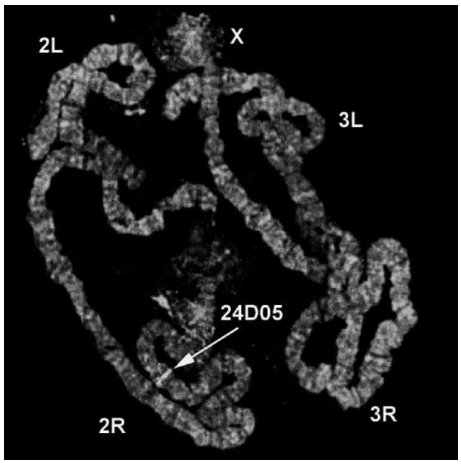

Fig. 1 Illustration of fluorescent *in situ* hybridization using a BAC clone probe. The *A. gambiae* polytene chromosome complement was isolated from the ovarian nurse cells of half-gravid mosquitoes. The probe, 24D08, is a BAC clone from the PEST library and is labeled with Cy3-dUTP red; the polytene chromosome is stained with Yoyo-1 iodide green (Molecular Probes).

orient the scaffolds on the three chromosome pairs, using physical mapping data. The chromosomal locations of assembled scaffolds were determined with sequence-tagged genomic DNA BAC clones that were mapped by *in situ* hybridization to ovarian nurse-cell polytene chromosomes (Fig. 1). For the initial assembly, approximately 2000 BAC clones were mapped and these data enabled the chromosomal location and orientation of scaffolds, constituting about 227 Mbp. Photo archive data showing the results of physical mapping are viewable at http://www.anobase.org. Since the initial assembly, the order and orientation of some of the smaller scaffolds have been confirmed or corrected, and ~7 Mbp more scaffolded sequence has been placed and oriented on the physical genome by *in situ* mapping of selected BAC and cDNA clones. Currently, 172 of the largest scaffolds have been assigned to chromosomal locations (a total of ~233 Mbp), and gaps between almost one-third of these scaffolds have been crossed by BAC clones or short BAC tiling paths (these BACs remain to be sequenced). Several dozen scaffolds (<10 Mbp) can be assigned only to nonspecific centromeric heterochromatic regions and about 1 Mbp of scaffolded sequence has been identified as possible Y-chromosome sequence; thus, about 243 Mbp of the 278 Mbp assembly has been assigned to locations with some level of confidence. Most of the remaining ~8700 unassigned scaffolds (~35 Mbp) are less than 20 kb. The majority of these appear to be repetitive heterochromatic sequences that, in *A. gambiae,* are clustered around the centromeres, the telomeres, and in a few islands in the euchromatic chromosome arms. Most of these scaffolds do not appear to contain genes and many are unlikely to be assigned to specific chromosomal locations by currently available approaches.

3.4 Genetic Variation

Analysis of high-quality mismatches within contig multiple sequence alignments revealed approximately half-a-million single nucleotide polymorphisms (SNPs) in the *A. gambiae* PEST-strain genome. The distribution of SNPs along the chromosomes is bimodal, with some regions showing roughly one SNP every 10 kb and others showing approximately one SNP every 200 bp. Given that the genome of the PEST strain appears to have resulted from a complex introgression of divergent Mopti and Savanna chromosomal forms, we expect that some genomic

regions may be derived only from one or the other form, yielding a low density of SNPs, while other genomic regions may continue to segregate both divergent forms, yielding a high SNP density. Interestingly, the X chromosome has a markedly lower average level of polymorphism and does not show this bimodal pattern, perhaps due to male hemizygosity and hence, a lower rate of introgression is seen on this chromosome. In addition, heterozygosity of the X is expected to be depressed because of the selection for homozygosity of the X-linked pink-eye mutation.

As expected, the overwhelming majority of SNPs lie in intergenic regions, but there is still an abundance of SNPs within functional genes. Introns and intergenic regions have virtually identical heterozygosities, but the silent coding positions appear to have more than twofold enrichment of variability. Generally, silent coding sites are considered as having more stringent constraints than introns or intergenic regions because of biased codon usage, and this is reflected in a lower diversity of silent sites in most organisms. The reason for elevated silent variation in *A. gambiae* is at present unknown. Nucleotides with strong functional constraints, such as splice donors, splice acceptors, and stop codons have the lowest heterozygosity, and nonsynonymous (missense) positions are also evidently low in heterozygosity.

The bimodal SNP distribution in the PEST strain, and hence, the existence of two approximately equally frequent haplotypes in a substantial fraction of the genome, presented a unique challenge for assembly of the sequence data set, and it is important to note that some assembly artifacts have resulted. Where the sequence variation between the two haplotypes is small, they have been assembled together into a single contig, with the most frequent nucleotide at each position contributing to the consensus sequence. This is the manner in which all current whole-genome assembly algorithms handle genetic variation, even though the resulting consensus sequence does not precisely represent any native haploid genome. In the case of *A. gambiae*, where the haplotypes are more divergent, they have occasionally been split into two separate contigs. This is problematic because the assembler only allows a single consensus sequence to represent any given position in the genome. As a result, in the draft assembly, there are situations in which the second redundant contig (1) has been placed in the nearest gap, causing an artificial tandem duplication within the scaffold; (2) has been left out of the scaffold as singleton; or (3) where the problem is at a scaffold end, the duplicate has been placed at the beginning of the neighboring scaffold. The phenomenon described here was initially revealed as a larger separation of mate pairs in parts of the assembly than what the library insert sizes had predicted. Comprehensive screening of the 1 644 078 total mate pairs in the assembly revealed a total of 726 regions, with this diagnostic mate-pair signature covering a total of approximately 7.7% of the assembly. The amount of sequence that is doubly represented in the genome assembly because of this artifact is estimated at about 23.5 Mbp.

While the bimodal pattern of SNP variation is a unique feature of the PEST strain and is not representative of any wild mosquito population, individual variants represent real polymorphisms in *A. gambiae* and will provide valuable marker sets for genetic studies. The approximately 500 000 PEST-strain SNPs are downloadable from

ftp://ftp.ncbi.nih.gov/genbank/genomes/Anopheles_gambiae or www.ensembl.org/anopheles_gambiae. A further 75 000 SNPs have been identified by comparing light sequence coverage (1.2×) from a lab strain of the Mopti cytogenetic form to the assembled PEST-strain sequence, and these SNP data are also available at www.ensembl.org/anopheles_gambiae.

Understanding the genetic diversity of anopheline mosquitoes and the molecular basis of cytogenetic form–associated traits will be accelerated by genomics and will likely point the way to more efficient strategies of vector-targeted malaria control. Efforts are presently underway to analyze large regions of the *A. gambiae* Y chromosome as population genetic markers and as indicators of the evolutionary relationships of the different *A. gambiae* forms and other species closely related to *A. gambiae*. Efforts to use other parts of the genome to define and identify such species and forms have been complicated by presumed interspecific and interform recombination over many regions of the different genomes. As a presumably nonrecombining part of the genome, the Y-chromosome sequence will be an invaluable source of material for teasing apart population structure and for developing rapid diagnostics for field studies. Studies are also underway to obtain wild isolates of *A. gambiae* from several different regions of Africa and sequence segments of DNA at regular intervals across the genomes of multiple individuals from each isolate. This survey of genetic diversity among different isolates of *A. gambiae* will facilitate the teasing apart of anopheline mosquito population structure and will play a crucial role in understanding mosquito biology, particularly those biological traits that influence vectorial capacity.

3.5 Gene Content

The initial automated annotation of the draft *A. gambiae* genome sequence was accomplished using established annotation pipelines at Celera and the Ensembl group at the European Bioinformatics Institute/Sanger Institute. Both pipelines use a combination of homology-based evidence and *ab initio* gene-finding algorithms to model gene structure. At the inception of the project, there were only approximately 6000 EST sequences available in public databases. However, given the evolutionary distance between *Drosophila* and *Anopheles* (~250 million years), obtaining wide representation from *Anopheles* EST libraries was essential for identifying the open reading frames of *A. gambiae* genes, and an additional approximately 80 000 EST sequences were derived from whole mosquitoes, as an integral part of the *Anopheles* genome project.

For proteome analysis, a nonredundant set of predicted protein sequences from the two pipelines (Celera and Ensembl) was constructed by selecting, for each locus, the annotation containing the largest number of exons. A total of 15 189 automated predictions were derived in this manner and, after removal of putative transposable elements and other contaminants, served as the set for initial analysis of the *A. gambiae* proteome. As is typical with automated genome annotations, it is likely that some false-positive predictions (pseudogenes, bacterial contaminants, and transposons) and false-negative predictions (*Anopheles* genes that were not computationally predicted) remain, and there are undoubtedly numerous errors in defining the precise boundaries of these putative gene structures. Automated annotation, while being a cost-effective method for an initial

high-level view of the genome, does not substitute for the careful manual curation that will be undertaken by the community over a period of time. Since the initial publication of the *Anopheles* genome, the annotation has been under continuous development by the Ensembl group in coordination with the International *A. gambiae* Genome Consortium. The present version of the annotated genome is available at www.ensembl.org/*Anopheles*_gambiae. A tutorial on the Ensembl Anopheles site is available at www.ensembl.org/*Anopheles*-gambiae/documents/mosquito_doc.pdf.

3.6 Comparison of the *Anopheles* and *Drosophila* Proteomes

Analysis of the annotated gene set has revealed many interesting features of the proteome of *A. gambiae*, particularly in comparison with *Drosophila melanogaster*, the closest relative of this vector (*A. gambiae* and *D. melanogaster* shared a common Dipteran ancestor approximately 250 million years ago.) to have a completely sequenced genome. In total, 47.2% of the *Anopheles* protein set is composed of 1 : 1 orthologs (defined as *reciprocal best Blast matches*), and 13.8% is composed of ''many-to-many'' orthologs, where paralogous gene families have expanded/contracted unevenly. A further 17.9% of the *Anopheles* protein set is represented by proteins that have a homologous relationship to *Drosophila* proteins, but the match cannot be easily defined as orthologous or paralogous. For example, proteins in this group might share one or more protein domains or might be divergent members of large and diverse protein families. 10.0% of *Anopheles* proteins had their best match to a noninsect species and 11.1% of *Anopheles* proteins do not show homology to proteins from any other species. Of these 1437 *Anopheles*-specific genes, 575 are supported by EST evidence and 522 show homology to other *A. gambiae* proteins. While some of these proteins may represent *de novo Anopheles* genes or rapidly evolving ancestral genes that are now mutated beyond recognition, it is likely that homologous sequences for these proteins will be discovered as the genomes of organisms with closer evolutionary relationships to *A. gambiae* are sequenced. Interestingly, in comparing the *A. gambiae* and *D. melanogaster* proteomes, sequence similarity is highest among structural molecules, transporters, and enzymes and is lowest among genes involved in defense and immunity. This is consistent with the results from other recent whole-genome projects that suggest that the most plastic gene families are those that mediate the direct interaction of the organism with its environment, such as genes involved in olfaction, detoxification, and immune response. In comparison, developmental genes are highly conserved between *D. melanogaster* and *A. gambiae*, with 85% having single 1 : 1 orthologs (best reciprocal matches) between the two species.

Given the evolutionary distance between *A. gambiae* and *D. melanogaster* conserved gene order (synteny) is recognizable only over short distances. Approximately 34% of *A. gambiae* genes colocalize in small microsyntenic clusters, defined as chromosomal regions where at least two orthologs or orthologous groups are separated by no more than five unrelated genes in the intervening DNA. In total, there are 948 such microsyntenic blocks in the *A. gambiae* genome, when compared to *D. melanogaster*, the largest block containing 31 orthologous genes.

Most clusters contain substantially fewer genes and show evidence of local duplications, inversions, and translocations. In contrast, homology between *A. gambiae* and *D. melanogaster* on the level of whole-chromosome arms is easily recognizable upon mapping of 1 : 1 orthologs. The most conserved pair of chromosomal arms are *D. melanogaster*2L (Dm2L) and *A. gambiae*3R (Ag3R), with 67% of Ag3R orthologs and 83% of microsyntenic clusters being significantly similar to Dm2L. *A. gambiae* chromosomal arm 2L appears to be largely homologous to Dm3L and Dm2R, with approximately 42% of *A. gambiae* orthologs found on each of these two *D. melanogaster* arms. Similarly, Ag2R shares homology with Dm3R. Ortholog content of Ag3L indicates that this chromosomal arm has modest homology to both Dm2R (30%) and Dm3L (22%). Homology between the X chromosomes of the two species is limited, with significant shuffling of chromosomal segments to and from autosomes.

The predicted *Anopheles* protein set has been classified on the basis of protein domains, and their functional categories, using InterPro and the Gene Ontology (GO). The relative abundance of the majority of proteins containing InterPro domains is similar between the mosquito and fly. As expected, insect-specific cuticle and chitin-binding domains and the insect-specific olfactory receptors are overrepresented relative to noninsects. However, comparing *A. gambiae* and *D. melanogaster,* only 6 of the 200 most abundant protein domains differ significantly in abundance. However, some of these differences are dramatic, such as the striking expansion of fibrinogen domain–containing proteins observed in *A. gambiae* relative to *D. melanogaster*. There are 58 *A. gambiae* and 13 *D. melanogaster* fibrinogen domain–containing proteins and only a single pair is a 1 : 1 ortholog. It is tempting to speculate that fibrinogen domains, which were originally found in proteins that mediate blood coagulation in mammals, could be conferring some function to mosquitoes that enables blood feeding, such as inhibition of blood-meal coagulation. Further, the serine proteases (central effectors of proteolytic processes) are well represented in both insect genomes, but *Anopheles* has nearly 100 additional members, perhaps again reflecting the hematophagous adaptation of this Dipteran.

Major differences in gene number are seen in the peroxidase system, which mediates the oxidation of diverse substrates. A total of 18 peroxidases were observed in *A. gambiae* and only 10 were observed in *D. melanogaster*. The *Anopheles* peroxidases have high homology to the salivary peroxidases of the mosquito *A. albimanus,* suggesting the possibility that this gene family has expanded to facilitate the blood-feeding process.

In a separate comparative analysis using the LEK algorithm to identify protein families with different representation in *A. gambiae* and *D. melanogaster*, a prominent expansion of a 19-member family of odorant receptors (ORs) was detected in *A. gambiae*. The members of this family do not show substantial sequence similarity to ORs from *D. melanogaster* or any other organism. While between *A. gambiae* and *D. melanogaster*, there is significant conservation of the G protein-coupled receptor superfamily as a whole, this *A. gambiae* OR subfamily appears to be unique and may play an important role in mosquito-specific behavior that includes host seeking, as discussed further in Sect. 4.1. In addition to the conspicuous protein family expansions discussed above, many additional

expansions were seen in diverse families. These include critical components of the visual system, structural components of the cell adhesion and contractile machinery, energy-generating glycolytic enzymes, anabolic and catabolic enzymes involved in protein and lipid metabolism, transporters, and detoxification enzymes.

Identification of gene family contractions have not been a focus of analysis of the *A. gambiae* genome, even though gene loss is considered to be an important mediator of evolution. It is ambiguous when doing a binary comparison whether there is expansion in one species or contraction in the other, relative to the state of the common ancestor. This can only be revealed by analysis of orthology across several species. Further, it is difficult to distinguish real gene losses from simple false-negative annotation results. Given that the overall gene count in *A. gambiae* and *D. melanogaster* is not significantly different, with each species having roughly 14 000 annotated gene loci, the overall number of expansions must be balanced by an equal number of reductions in each species, as they evolve to fill their ecological niches.

3.7 Genes Regulated by Blood Feeding

Newly emerged female mosquitoes are sustained by sugar meals as they seek the blood meal that is necessary to support egg development. Active host seeking is facilitated by olfactory, temperature, and visual cues. After locating a host and extracting several times their weight in blood, the female mosquito appears to undergo profound metabolic reprogramming, commensurate with the task of processing the massive blood bolus.

The *A. gambiae* genome project included an EST-sequencing program utilizing two source libraries. One library was constructed using DNA from whole adult female mosquitoes before blood feeding, when in a relatively quiescent metabolic state, and the second library was constructed 24 h after a blood meal, when the mosquitoes were under the metabolic burden of converting the blood meal into eggs. This approach facilitated identification of genes activated or inactivated by blood feeding in a hematophagous insect. Approximately 40 000 ESTs were sequenced from each library and assembled into approximately 7000 consensus sequences, each representing a distinct gene locus. 435 genes showed significantly altered transcription following blood-meal ingestion, as determined by Chi-squared analysis. Analysis of gene expression pre- and post blood feeding has revealed both expected and unexpected changes (Table 1). As expected, there is dramatic upregulation (up to 144 fold) of transcripts encoding serine proteases and other proteases, transcripts involved in transcriptional control and nuclear regulation, and transcripts representing the protein synthesis machinery that are involved in converting the digested blood proteins into new functional mosquito protein products. Further, transcripts involved in gluconeogenesis, lipid metabolism, and purine metabolism are upregulated, as are a small number of transcripts, such as ubiquitin-conjugating enzymes and cytosolic aminopeptidases, whose protein products mediate intracellular degradation of protein. Finally, there is upregulation of oogenesis-associated proteins and lipids 24 h post blood meal, including several vitellogenins (yolk constituents) and members of the phenoloxidase pathway that mediates eggshell melanization. In terms

of decreased expression, genes involved in sugar metabolism (for example, salivary and midgut maltases, glycolysis, and oxidative phosphorylation) are downregulated, which is not unexpected, given the presumed decreased reliance on sugar metabolism with the high intake of a protein-rich blood meal. More intriguing is the marked downregulation post blood meal of striated muscle proteins, including actin, myosin, tafazzin, and troponin, as well as ATP-dependent cation transporters and Ca^{2+} binding proteins involved in motor signaling. Taken together with the observed decrease in transcription of opsins, photoreceptor associated proteins, cuticular proteins associated with the eye lens, and pheromone-binding proteins, the post blood-meal expression pattern suggests that after a blood meal, mosquitoes become detached from their environment and sacrifice mobility in order to devote metabolic attention to the monumental task of blood-meal processing and egg development. The set of genes upregulated by blood-meal digestion presents a rich source of novel insecticide targets and will allow identification of promoters that can activate transgenes in a blood-meal responsive manner.

4 Utility of the *A. gambiae* Genome

4.1 Odorant Receptors and Novel Repellents/Attractants

The distinct preference of *A. gambiae* for human blood meals contributes substantially to the menace of this vector. Very

Tab. 1 Representative messages significantly more transcribed or less transcribed in female *A. gambiae* mosquitoes 24 h after human blood-meal ingestion.

little is known about the molecular basis of this selective behavior, although it almost certainly involves specific human odors and mosquito pathways for detecting and responding to these odors. Continuing to explore the diversity of ORs and odorant binding proteins encoded in the *A. gambiae* genome will lead to a better understanding of the mechanisms of host preference and will uncover potential targets for a new generation of specific attractants/repellents. Preliminary analysis of the draft genome sequence identified a total of 276 G protein-coupled receptors, including 79 candidate ORs. The majority of these ORs (64 of 79) show expression only in olfactory tissues, as determined by RT-PCR experiments. Comparison to *D. melanogaster* revealed a similar total number of ORs, but only a single unequivocal orthologous pair of ORs between the two species. The extensive lineage-specific expansion of ORs likely reflects the ecological and physiological relevance of these receptors and the importance of each species being able to detect relevant chemicals – for example, rotting fruit odors for *D. melanogaster* and human host odors for *Anopheles*. AgOr1, a putative *A. gambiae* OR, has recently been identified as a possible mediator of human host finding. Initial clues that AgOr1 may be important in host finding include its expression exclusively in the olfactory tissue of female mosquitoes, and the downregulation of its expression in these tissues after a blood meal. Hallem EA et al. provided further evidence by engineering *D. melanogaster* neurons lacking endogenous ORs and by transfecting these with AgOr1. Electrophysiological measurements of the transfected cells showed that a component of human sweat, 4-methylphenol, elicited a strong response.

4.2 Insecticide Resistance Genes

During the 1950s and early 1960s, the WHO malaria eradication campaign succeeded in eradicating malaria from Europe and dramatically reduced its prevalence in many other parts of the world, primarily through programs that combined mosquito control agents like DDT with antimalarial drugs like chloroquine. However, malaria and anopheline mosquitoes remain entrenched in sub-Saharan Africa and the appearance of chloroquine-resistant parasites and insecticide-resistant mosquitoes is contributing to the current rise of malaria in Africa. Even control programs based on insecticide-impregnated bed nets, which are now advocated by WHO and are being widely implemented in Africa are threatened by the development of resistance to pyrethroids, the insecticide class of choice for this application. Insecticide resistance is often metabolic, where the insecticide will induce the expression of an enzyme that degrades it. Metabolic resistance is mediated largely by one of the three classes of enzymes, depending on the particular insecticidal agent in question. These are carboxylesterases (CEs), glutathione-*S*-transferases (GSTs) and cytochrome P450s. Ranson et al. cataloged members of these three major insecticide resistance–related families in the *A. gambiae* genome. Comparison to *D. melanogaster* revealed that a considerable expansion of these families has occurred in the mosquito. For example, there are 51 versus 31 CEs and 111 versus 90 cytochrome P450 enzymes in *A. gambiae* and *D. melanogaster* respectively. Secure orthologs between *D. melanogaster* and *A. gambiae*, identified by rigorous analysis of phylogenetic trees comprise less than

15% of these supergene families, indicating that gene families have radiated independently from common ancestral genes, presumably driven by the different metabolic requirements of the two species for natural compounds. Over the past decade, several resistance loci for different agents have been mapped in the mosquito genome, using classical genetic methods, and inspection of gene content within the boundaries of mapped resistance loci has been revealing. For example, it has been observed that several large clusters of cytochrome P450 genes colocalize with a known pyrethroid resistance locus involved in oxidative metabolism of the insecticide. Further, a major DDT resistance locus colocalizes with a cluster of eight epsilon (insect-specific) GST genes on chromosome 3R. Biochemical characterization of the members of this GST cluster has shown that only one of these eight enzymes, GSTE2-2, is able to metabolize DDT. Western blots using antibodies raised against this GST indicated that its expression is elevated in a DDT-resistant strain (ZAN/U) of *A. gambiae*, relative to an insecticide-sensitive strain (Kisumu). Subsequent and more comprehensive quantitative PCR studies in these two mosquito strains have indicated that not just GSTE2-2, but in total, five of the eight GSTs genes in this cluster are significantly overexpressed in the DDT-resistant strain. Gene dosage analysis showed no evidence for gene amplification, suggesting perhaps that coexpression of genes in the epsilon cluster is controlled by a common regulatory element.

In addition to metabolic resistance, insensitivity to an insecticide can arise through mutations that disrupt binding of the insecticide molecule to its target protein. A well-characterized example is the insensitivity to two major insecticide families, organophosphates and carbamates, that arises through mutation in their target protein Acetylcholinesterase (AChE). Only one AChE gene is present in *D. melanogaster* (called ace-2) and it is well established that resistance in *D. melanogaster* is caused by mutations at this locus. Two AChE genes, ace-1 and ace-2, have been identified in *A. gambiae*, through sequence searches of the reference genome, using human and *D. melanogaster* AChEs as queries. The *A. gambiae* ace-1 gene shows 52% amino acid identity and the *A. gambiae* ace-2 gene shows 83% amino acid identity to the single *D. melanogaster* AChE, and both *Anopheles* genes contain the conserved FGESAG active site motif. Phylogenetic analysis suggests that the presence of two AChE genes is the ancestral state, and one of these genes has been lost in *D. melanogaster*. It is well established that mutation of the target site of the single *D. melanogaster* AChE gene causes resistance to organophosphates and carbamates in this species, Interestingly, however, in organophosphate and carbamate resistant *Culex pipiens* and *A. gambiae* strains, insensitivity results from a substitution (G119S) near the catalytic site of the ace-1 gene, not a mutation of the ace-2 gene, which is presumably the direct *D. melanogaster* ortholog.

Understanding the common mechanisms of insecticide resistance in *A. gambiae* is of practical importance. The possibility now exists of screening new compounds for tolerance liability by determining whether they cause mutation in known hotspots in genes previously shown to confer resistance or induction of genes with a detoxifying function. Further, specific mutations in resistance-conferring genes can be used as markers to monitor the spread of resistance to insecticides

in use in Africa, and can provide important information to help guide ongoing chemical-based vector-control programs.

4.3 Insecticide Targets

While most chemical agents used in the battle against mosquito-borne disease are broad-spectrum agents developed for the purpose of agricultural pest control, the possibility now exists of finding and exploiting physiological and biochemical systems that are unique to the mosquito, in order to produce new and highly selective agents for mosquito control. The reference mosquito genome sequence has helped reveal a variety of systems that may be good candidates for the development of more selective agents for mosquito control. For example, regulatory peptides act as neurochemicals and hormones that guide mosquito reproduction and development. A total of 35 genes encoding putative regulatory peptides have been annotated in the *A. gambiae* genome and agents that mimic or block the action of these peptides may be effective insecticides. Ecdysteroid peptide hormones, which govern gene expression during female reproduction and larval development are of particular interest. Ovary ecdysteroids released after a blood meal stimulate the fat body to begin secreting yolk proteins. The presence of an ortholog of *A. gambiae* ovary ecdysteroid hormone in the mosquito *Aedes aegypti* but the absence of an ortholog in *D. melanogaster* suggests that there is a unique role for this peptide in hematophagous insects and, thus, an opportunity for development of specific antimosquito agents. Similarly, diuresis is a process that has a critical function in the mosquito that may be exploited. After blood feeding, female mosquitoes engage in rapid diuresis to decrease the volume of the blood meal and allow flight. Genes for all four diuretic hormones known to regulate fluid secretion in insects have been identified in the *A. gambiae* genome and present additional targets for incapacitating the mosquito. Also of interest, the receptor for FRMF amide, a cardioexcitatory tetrapeptide first identified in clam, has been identified in the mosquito genome. In functional studies, the tetrapeptide significantly increased the frequency of spontaneous contractions of the heart in mosquito larvae, suggesting the possibility of developing agonists for this receptor as a larvicide.

Mining of reference genome sequences has revealed that enzyme glutathione reductase is absent from Diptera and is functionally substituted by the thioredoxin system. Thioredoxins are small ubiquitous thiol proteins that efficiently cleave disulfide bonds in a number of other proteins and take part in redox control of numerous cellular processes such as protein folding, signaling, and transcription. The key enzyme in this system is thioredoxin reductase, a single copy gene located on the *A. gambiae* X chromosome and shares 52% sequence identity with its human ortholog. The sequence of the catalytic redox center is different between the *A. gambiae* (Thr-Cys-Cys-SerOH) and human (Gly-Cys-selenocysteine-GlyOH) proteins and this difference provides an attractive avenue for the development of a selective inhibitor.

Differences between mammalian and insect metabotropic glutamate receptors have also been revealed by whole-genome comparison. The *D. melanogaster* metabotropic glutamate receptor (mGluR) shares a very similar pharmacological profile with its mammalian orthologs, being

activated or inhibited by the same natural or synthetic ligands. However, a new receptor in mGluR subclass has been found in the mosquito, the honeybee *Apis mellifera*, and *D. melanogaster*, called AmXR, HBmXR, and *Dm*XR respectively. No direct orthologs of these novel insect receptors are detectable in *C. elegans* or in human genome. The native ligand for these receptors is unknown, although it has been shown that extract from *D. melanogaster* and *A. gambiae*, but not *C. elegans* or mouse brain, caused dose-dependent receptor activation. Sensitivity to formaldehyde (which masks amino groups) and insensitivity to HCl (which disrupts peptide bonds) suggests that the native ligand is an amino acid–like molecule, but the native ligand is clearly not glutamate, given that residues contacting γ-carboxyl group of glutamate are not conserved with the mGluR, and heterologous expression showed no stimulation by glutamate or mGluR agonists AMPA, kainate, and NMDA quisqualate. Because the XR receptors appear to be insect specific, compounds that disrupt their function may, if lethal, form a promising new class of specific insecticide.

4.4 Immune-response Genes and Genetic Vector Control Strategies

To successfully complete its complex life cycle, the malaria parasite must evade both the human and mosquito immune systems. Parasites ingested with the blood meal develop within the mosquito gut into ookinetes, which subsequently burrow into the gut epithelium and form oocysts. When the oocysts burst, sporozoites are released and these travel to the salivary glands to await transfer to a new host. However, large losses in parasite number occur during this invasion because of mosquito defenses such as melanotic parasite encapsulation. These defenses do not comprise an adaptive immune system, such as that found in mammals, but rather belong to the ancient innate immune system that most metazoans rely on for dealing with invading microorganisms. Facilitating these innate mosquito defenses offers a new and promising strategy for malaria control.

In the past decade, genetic selection in the laboratory has yielded several interesting *A. gambiae* strains, including some that are completely refractory to *Plasmodium*. These strains have been the subject of intensive study in a number of different laboratories, and the *A. gambiae* genome is facilitating the identification of candidate genes for *Plasmodium* resistance. More recently, Christophides et al. screened the *A. gambiae* genome for genes implicated in the innate immune response of the mosquito and identified 242 players from 18 different gene families including, for example, pattern-recognition receptors that bind pathogen-specific molecules, second messengers that can amplify or dampen immune signals, and effector molecules such as the prophenoloxidases that mediate melanization. There is marked diversification of these genes relative to their *Drosophila* homologs, likely reflecting the adaptation of *Anopheles and Drosophila* to different immune challenges represented by different ecological and physiological conditions. Recent functional screening (gene silencing using dsRNA) of a subset of these candidate immune-response genes in *A. gambiae* has yielded compelling findings for several pattern-recognition receptors. Functional knockout of the *A. gambiae* leucine-rich repeat protein (LRIM1) led to a substantial (3.6-fold)

increase in oocyst numbers, indicating that this gene has a strong protective effect against the invading parasite. Similarly, functional knockout of the pattern-recognition receptor thioester-containing protein 1 (TEP1) in *A. gambiae* led to a fivefold increase in the number of oocysts developing on the midgut epithelium and a complete abolishment of parasite melanization. Conversely, functional knockout of two different *A. gambiae* C-type lectines (CTL4 and CTLMA2) resulted in a paradoxical enhancement of immune response, with massive melanization of invading ookinetes. It is not clear how these mosquito CTL genes act to protect the developing malaria parasite within the mosquito and no obvious homologs of these genes have been detected in any other organism. LRIM1, TEP1, CTL4, and CTLMA2 are the first mosquito genes to be identified as having an important role in the immune response of the mosquito to the invading malaria parasite. While it is unlikely that gene silencing using dsRNA will be practical as a malaria-control measure, these exciting observations are nonetheless the first steps along the road to the development of a genetic-based transmission-blocking strategy for malaria. Germ-line transformation of the mosquitoes *A. stephensi* and *A. gambiae* has recently been achieved, bringing the possibility of malaria control through the introduction of transgenic mosquitoes another step closer to reality. While genetic control strategies for malaria vectors are complicated by several factors, including the diversity of naturally occurring cytogenetic forms that are reproductively isolated, the selective pressure applied to the *Plasmodium* population, plus all of the usual risks associated with the release of transgenic insects, there is much promise that transgenics will play a key role in malaria control in the coming decades.

Keywords

Gonocyte
A diploid male germ cell in fetal testis that undergoes mitosis and then becomes quiescent until the onset of spermatogenesis at puberty after birth.

Leydig Cell
A somatic cell producing testosterone, found in the interstitium between seminiferous tubules.

Peritubular Myoid Cell
A somatic cell type with contractile capacity; forms a layer around each seminiferous tubule and contributes to its basement membrane.

Primordial Germ Cell
Indifferent germ cells that exist before the onset of gonadal differentiation in a fetal testis or ovary.

Sertoli Cell
Somatic cells that surround and nourish the developing male germ cells that form the scaffolding of the seminiferous epithelium.

Spermatid
A haploid male germ cell that is transformed from a round shape to an elongated shape during spermiogenesis, as nuclear remodeling, acrosome formation, and tail elongation occur.

Spermatocyte
The male germ cell undergoing meiosis I and II; may be tetraploid (primary spermatocyte) or diploid (secondary spermatocyte).

Spermatogonium
A diploid male germ cell that can undergo mitosis.

Spermatozoon
A motile, elongated, haploid male gamete released from the seminiferous epithelium.

The determination of gonadal sex establishes the basic structure of the testis. This results in the formation of seminiferous cords containing immature Sertoli cells and gonocytes, with the testosterone-secreting Leydig cells lying within the intertubular region. Gonadotrophic stimulation of the testis and the resultant testosterone secretion stimulates spermatogenesis, which involves mitosis, meiosis, and the production of spermatozoa. Germ cell function is crucially dependent on the Sertoli cells that control the intratubular environment, partly by forming the blood–testis barrier. The biochemical nature of the signals that regulate somatic cell function and germ cell maturation is now partially understood, though the complexities of the regulatory pathways and their complete significance are yet to be clarified. This brief overview of the current state of knowledge regarding the controlling signals presents some aspects of their impact on the target cells, both somatic and germinal.

1 Testicular Architecture, Cellular Composition, and Principles

1.1 The Adult Testis

The synthesis of spermatozoa is initiated during puberty and is continuous throughout adult life. Male fertility is dependent on the maintenance of a self-renewing stem cell population and a complex set of signals derived from hormonal and local factors that drive spermatogenesis in a highly regulated manner.

1.1.1 Two Functional Compartments

The adult mammalian testis consists of two structurally distinct but functionally interrelated compartments: the *seminiferous* epithelium, wherein germ cells divide and differentiate surrounded by the Sertoli ''nurse'' cells, and the *interstitial compartment*. Spermatogenesis occurring within the seminiferous tubules can be divided into three processes: (1) replication of stem cells by mitosis (primordial germ cells in the fetus, gonocytes in the juvenile, and spermatogonia in the sexually mature individual); (2) reduction of chromosomal number by the process of meiosis (primary and secondary spermatocytes); and (3) a complex metamorphosis, called *spermiogenesis*, involving the transformation of round cells (spermatids) into elongated spermatozoa.

The developing germ cells, other than spermatogonia, are enveloped by Sertoli cells, which in turn have access to the interstitial space that contains the Leydig cells,

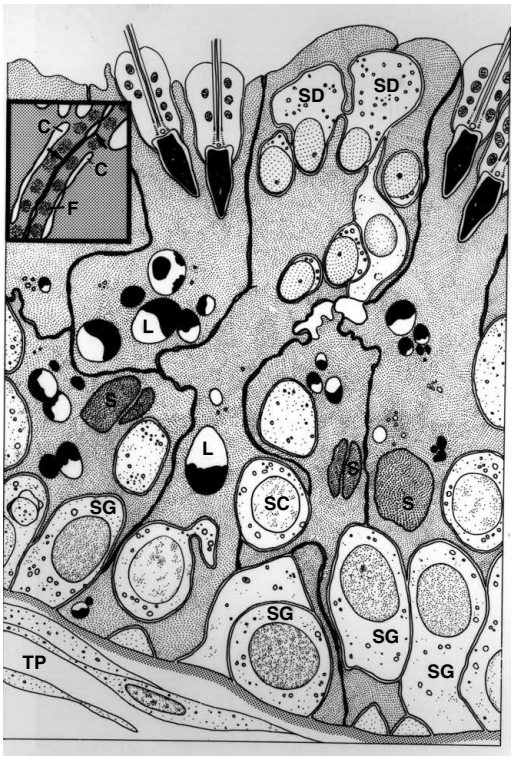

Fig. 1 Diagrammatic representation of the epithelium of the seminiferous tubule. Illustrated are spermatogonia (SG), primary spermatocytes (SC), spermatids (SD), mature spermatozoa, and Sertoli cells (S) with lipid inclusions (L). The peritubular myoid cells lie outside the tubule in the tunica propria (TP). The Leydig cells and vasculature lie external to the tunica propria. *Inset*: organization of the tight junctions between Sertoli cells that form the blood–testis barrier.

peritubular myoid cells, macrophages, and the vasculature fluids (Fig. 1).

The adjacent Sertoli cells are connected by a unique cluster of junctional specializations comprised of tight and gap junctions at their base. This junction divides the seminiferous epithelium into two functional compartments, apical and basal. Mitotic germ cells are in the basal compartment, and they cross the tight junction as they enter their meiotic phase of differentiation. Within the apical compartment of the seminiferous epithelium, the spermatocytes and spermatids are exclusively reliant on Sertoli cell products and are also invisible to the surveillance of the immune system, which might otherwise view them as ''foreign'' cells. Differentiating germ cells are connected to their clonal siblings by cytoplasmic bridges until the time of their release as spermatozoa into the tubule lumen as the result of incomplete cytokinesis. Thus they remain functionally diploid even when their nuclear compartments contain only one parental copy of each chromosome.

It is important to recognize that the seminiferous tubule is an avascular compartment. Intercellular transport into the epithelium cannot occur because there are tight junctions between adjacent Sertoli cells luminal to the spermatogonial layer. Consequently, germ cells other than spermatogonia are dependent on the Sertoli cells for transport and for the regulation of the internal milieu of the tubule.

1.1.2 **Spermatogenesis is Cyclical**

The process of spermatogenesis is highly organized and ordered, with precise

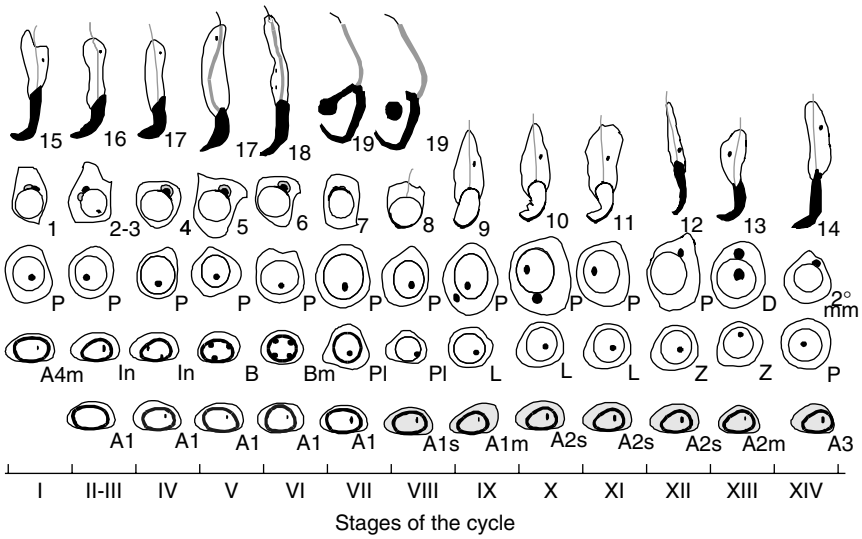

Fig. 2 Stages of the cycle of the seminiferous epithelium observed in the adult rat testis. Each column represents the invariant set of germ cell maturation types present simultaneously within a cross-section of a seminiferous tubule. The least mature germ cell types, present at the base of the seminiferous epithelium, (stem cells {A_s}, A_{pr}, A_{al}, A_8 and A_{16} spermatogonia) are infrequently observed and are not illustrated here. Type A_1, A_2, A_3 and A_4 spermatogonia (A_1–A_4) are morphologically indistinguishable, while Intermediate (In) and Type B spermatogonia have distinctive heterochromatin. Stages of spermatocytes : preleptotene (PL), leptotene (L), zygotene (Z), pachytene (P), diplotene (D) and metaphase (2°mm). Spermatid steps are indicated by numbers 1 through 19, with 1 to 8 being round spermatids and 9 to 19 elongating spermatids. Adapted from Russell et al. 1990.

associations of germ cells at specific stages of maturation (Fig. 2), creating invariant cycles within the epithelium and waves of stages along the tubule. Although disruption of germ cell development can be induced experimentally, leading to an arrest at discrete stages of spermatogenesis, the normal arrangement of cellular associations is rapidly reestablished upon recovery. The mechanisms that maintain these highly ordered patterns are poorly understood, though they are believed to be essential for attainment of the full spermatogenic potential of the testis. The underlying basis for the spermatogenic wave appears to be established in fetal life, as illustrated by the cyclic expression of the galectin gene in fetal Sertoli cells, prior to the onset of germ cell differentiation. That germ cells can in turn influence the cyclic function of the adult seminiferous epithelium has been demonstrated by interspecific transfer of rat sperm into the mouse testis; the rat sperm specifies the timing of the epithelial cycle when embedded in the mouse Sertoli cell.

The preceding description indicates that the testis contains germ cells and somatic cells involved in discrete, characteristic patterns of macromolecular synthesis. This arises from the steps in spermatogenesis that require replication of stem cells by mitosis, the reduction of chromosomal number and DNA content to the haploid state, and the complex processes constituting spermiogenesis. The latter

requires specific protein synthesis by the haploid genome and the cessation of transcription as the chromatin condenses to form the sperm head. These events and their implications are emphasized in the following sections.

1.2 The Developing Testis

1.2.1 The Fetal Testis

The indifferent gonad The gonads arise from urogenital ridges that form on either side of the midline of the developing embryo. Formed from a thickening of the coelomic epithelium on the surface of the mesonephros, the gonad is initially devoid of germ cells and has the potential to develop as either a testis or an ovary, and hence it is termed *indifferent*. The migration of cells into this area contributes to both somatic (fetal Leydig cell and peritubular myoid cell lineages from the mesonephros; some Sertoli cells from the coelomic epithelium) and germ cell (primordial germ cells from the endoderm of the yolk sac near the allantoic invagination) lineages.

The indifferent gonad is present during approximately weeks 4 to 7 postcoitum in the human and 9 to 12 days postcoitum (dpc) in the mouse. Establishment of this structure requires expression of steroidogenic factor 1 (SF-1; a transcription factor), the Wilm's tumor 1 (WT1) protein isoforms, and fibroblast growth factor-9 (Fgf-9). For each of these, the absence of the gene results in initial formation of the indifferent gonad in the mouse embryo, but the tissue degenerates and does not support germ cell survival.

Genes controlling testis formation The primary molecular trigger for gonadal sex determination is SRY (sex-determining region on the Y chromosome) gene expression, observed in the mouse gonad at 10.5 to 12.5 dpc within the somatic cells that are precursors to Sertoli cells. Introduction of the mouse SRY gene onto a mouse somatic chromosome through transgenesis produced sex-reversed male mice, that is, XX males, having male external genitalia, male sexual behavior, and testes that lack germ cells. Thus, SRY expression directs testis formation but is not sufficient to provide the environment required for spermatogenesis. A highly conserved portion of this gene encodes an HMG (high mobility group) box, characteristic of a family of DNA-binding proteins, and mutations in this region of SRY can cause sex reversal in mouse and humans. The definitive identification of SRY target genes is yet to be achieved.

The first visible sign of testicular differentiation occurs at day 12.5 postcoitum in mouse, with the organization of Sertoli cells into cords surrounding the male primordial germ cells, now termed *gonocytes*. In the female, the initiation of germ cell meiosis at day 13.5 postcoitum marks ovarian development.

One likely downstream target of SRY is SOX9, and, similar to SRY, expression of SOX9 in pre-Sertoli cells is sufficient to drive development of an XX gonad to form a testis. Also containing an HMG box, SOX9 is present in both male and female gonads when indifferent, but it is upregulated in males and downregulated in females following SRY expression onset. As testis differentiation begins, SOX9 moves to the nucleus to effect changes in transcription of downstream genes. SOX9 may switch on the genes required to form testicular cords, and it is known to induce expression of Müllerian Inhibiting Substance

(MIS). The growth factor MIS is produced by fetal Sertoli cells during cord formation, and it mediates regression of the female duct components (see section on Mullerian inhibiting substance). The MIS-gene promoter includes a binding site for SF-1. Expression of fgf9 in the mouse male gonad begins immediately after SRY, and it is required for normal Sertoli cell differentiation, germ cell proliferation, and migration of mesonephric cells into the developing gonad. The expression of neurotropin-3 (NT3) in Sertoli cells appears to regulate mesonephric cell migration and can positively regulate SOX9 expression.

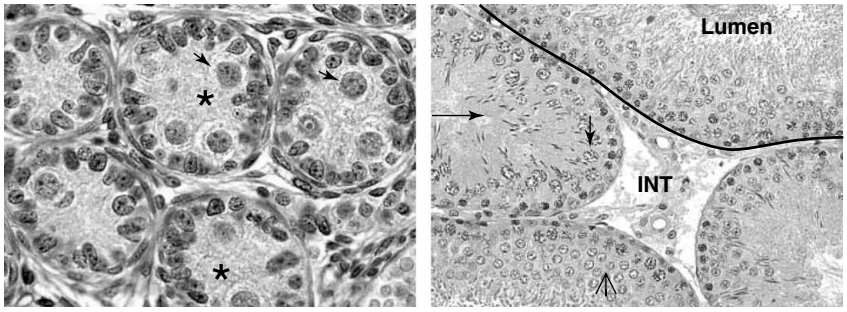
The germ cells are directed to form either gonocytes or oocytes by signals from their somatic cell environment. This commitment occurs in the testis between 11.5 and 12.5 dpc, and, in the ovary, with the commencement of meiosis at 13.5 dpc. Evidence of a positive feedback loop is derived from the production of prostaglandin D2 by germ cells, which will stimulate XX somatic cells to synthesize MIS *in vitro* and form cords, indicative of their differentiation into the Sertoli cell lineage.

This period of development is classically held to be gonadotrophin-independent. The subsequent emergence of a fetal-type Leydig cell population depends on expression of the type A platelet-derived growth factor (PDGF) receptor, and retinoic acid has been implicated in the formation of cords by affecting laminin deposition. These data highlight the concept that, during fetal life, a diversity of locally derived signals are required in order to orchestrate development of the full complement of somatic cell lineages required for the support of spermatogenic cells.

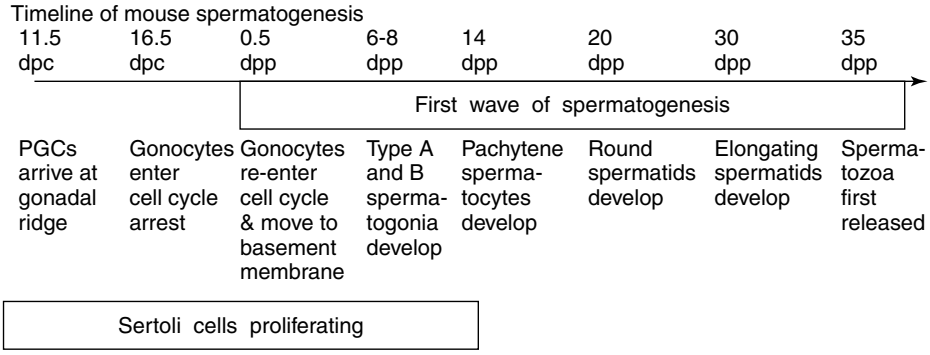
The testis continues to grow through fetal life while the gonocyte remains quiescent. The rate of Sertoli cell proliferation in the rodent peaks just before birth, and the interstitial cell populations continue to mature and multiply.

1.2.2 Neonatal and Juvenile Somatic and Germ Cell Differentiation

The onset of spermatogenesis occurs in a testis that contains quiescent germ cells engulfed by proliferating Sertoli cells in the testis cords (Fig. 3). The cords are surrounded by layers of immature myoid cells, which, along with the Sertoli cells, contribute to the expanding and changing basement membrane at the cord perimeter. Nests of fetal Leydig cells are evident. Within a few days after birth in rodents, and in the prepubertal period, the germ cells are stimulated to reenter the cell cycle and migrate to contact the cord basement membrane. The gonocytes that do not migrate will die by apoptosis; those that do migrate will form the stem cell population that is the progenitor of all adult spermatogenesis. The stimulus for this differentiation, termed *the first wave of spermatogenesis*, appears to be a combination of hormonal (e.g. follicle-stimulating hormone; FSH) and growth-factor (e.g. transforming growth factor β superfamily members) signaling to both germ cells and somatic cells. In the rat testis, germ cell migration is mediated by cell adhesion (N-CAM) and growth factor signaling, with Sertoli cell–derived stem cell factor (SCF) interacting with the c-kit tyrosine kinase receptor on the maturing germ cells (Sect. 3.3.2). The situation in the mouse may be slightly different, and perhaps independent of SCF signaling at this step, with the expansion of this stem cell population being profoundly affected by the presence of glial-derived neurotropic factor (GDNF). Other factors implicated in events at this time include NT3, nerve growth factor



(a)



(b)

Fig. 3 Progressive changes in testis during fetal and postnatal development. Micrographs (a) and timeline (b) illustrating changes in the developing rodent testis. (a) newborn rat testis is comprised of cords (shown in cross-section) surrounded by maturing peritubular myoid cells. Gonocytes (arrows) are the only germ cell type present; these are surrounded by Sertoli cell cytoplasm (asterisk). Adult testis tubules (shown in cross-section) are surrounded by flattened layer of peritubular myoid cells; line indicates tubule boundary. Interstitium (INT) contains Leydig cells, macrophages, lymphatics, and blood vessels. Pachytene spermatocytes (arrowheads), round spermatids (open arrows) and elongating spermatids (dashed arrow) are progressively closer to the tubule lumen where mature spermatozoa are released. (b) timeline of murine male germ cell developmental events through to initial production of spermatozoa. Adapted from McCarrey (1993).

(NGF), epidermal growth factor (EGF), PDGF and follistatin (an activin and BMP antagonist).

Examining the rodent testis at discrete time points after birth allows one to observe the appearance of progressively maturing germ cell types. (Fig. 3). In contrast, these time points are highly variable in primates.

Somatic cell differentiation is an important feature of the first wave of spermatogenesis. The cessation of Sertoli cell division during this interval establishes the full complement of these cells that are present throughout the individual's life. This is of crucial importance for establishing the maximum capacity for adult sperm production

(discussed further in Sect. 3.1.2). Sertoli cell proliferation is controlled by interactions between hormones and growth factors, with FSH, thyroid hormone, GDNF, and activin representing some key *in vivo* modulators. A new Leydig cell population arises and differentiates in the interstitium, and the cells surrounding the cords gradually flatten to form the thin layer of peritubular myoid cells observed in the adult testis. Once again, the differentiation and function of these cells appear to respond to a network of hormonal and local factor cues.

To date, a limited number of genes have been identified that show differential expression within a particular cell type between the immature (i.e. first wave) testis and the adult testis. This presumably reflects the changing nature of the seminiferous epithelium with the onset of germ cell, Sertoli cell and peritubular myoid cell differentiation. For example, mRNAs encoding the prosurvival members of the bcl-2 family, bcl-2 and bcl-$_{XL}$, are present in spermatogonia and Sertoli cells during the first two postnatal weeks of mouse testis development but are absent thereafter. The bcl-2 mRNA is switched off entirely, while bcl-$_{XL}$ shifts to the newly emerging spermatocyte population. Such differences are not surprising within the Sertoli cells that transform from mitotic to terminally differentiated cells. Less predictable was the observation that spermatogonia during the first wave of spermatogenesis are functionally different from those present in adulthood. These findings emphasize the notion that germ cell mRNA and protein synthesis are governed by changing environmental cues, including those from the adjacent clones of the progressively more and less mature germ cell clones within the seminiferous epithelium.

2 Regulation of Gene Expression During Spermatogenesis

2.1 DNA

During the preleptotene stage of Meiosis I, there is a peak of DNA synthesis coincident with the peak in DNA polymerase activity that transforms the diploid spermatogonium into a tetraploid spermatocyte. A low level of DNA synthesis documented in pachytene spermatocytes is associated with the DNA repair that follows recombination between homologous chromosomes. DNA methylation patterns vary, with some single-copy genes being methylated at normal levels, some regions of repetitive DNA sequences being under-methylated, and others, such as the genes encoding the chromatin-associated protamine and transition proteins, and the germ cell–specific phosphoglycerate kinase (PGK-2) undergoing changes in methylation during spermatogenesis.

Chromatin remodeling occurs in the haploid germ cells to enable DNA compaction in spermatozoa. The chromosomes become highly organized in hairpin structures of DNA arranged into looped domains along a track of nuclear matrix, with the centromeres found in the center and the telomeres at the perimeter of the sperm nucleus. During spermiogenesis, the histones that package genomic DNA in somatic cells, spermatogonia, and spermatocytes are replaced by transition proteins that are in turn replaced by protamines. The protamines are small, basic proteins represented by 1 or 2 family members. In mouse, both protamine-1 and protamine-2 are required for normal sperm formation. A relatively small proportion of sperm chromatin remains associated with

a nucleohistone; in humans, this accounts for about 15% of sperm DNA. Association of DNA with histones has been proposed to reflect the involvement of genes in these regions with the early postfertilization events.

Inactivation of the X chromosome occurs during meiosis, but it is incomplete. In particular, the Xp terminus remains active, and includes genes encoding the GM-CSF receptor, mic2, and steroid sulfatase in humans. Coincident with X chromosome inactivation, there is activation of autosomal homologs of several genes, including those encoding PGK-2, the EI subunit of pyruvate dehydrogenase, lactate dehydrogenase (LDH-X), and Zfa. These appear to be the result of retroposon activities, as they are characterized by a lack of introns, unlike their counterparts on the X chromosome.

2.2 RNA

RNA synthesis occurs in all spermatogenic cells up through the round spermatid stage, with a constant ratio of DNA to RNA content per cell through meiosis. One study provided the estimate that one half of all mRNAs made in the adult testis increase in abundance after meiosis, and one quarter of adult testicular mRNAs are synthesized only in postmeiotic cells, indicating the requirement for specialized proteins to build a functional spermatozoon.

An important feature of postmeiotic gene expression is that mRNAs produced by the haploid male germ cell are shared between clonal siblings, rendering them functionally diploid while still in the seminiferous epithelium. This was illustrated by the observation of human growth hormone (hGH) transcripts in all spermatids of heterozygote mice bearing a transgene that encodes the hGH gene linked to the protamine promoter. The protamine-transcript sharing between spermatids has also been described, and proteins are also exchanged between clonal siblings at this stage.

As is apparent in every developmental system, unique interactions between many sets of molecules dictate the specific physiological response of the differentiating cell. Because spermatogenesis involves morphological and physiological events that do not happen in any other cell type, it is easy to anticipate that a unique set of genes and regulatory mechanisms will function in the testis. There are also many genes that are expressed in somatic cells that are important for sperm development. Control of the production of proteins required for spermatogenesis is exhibited during both transcription and translation. Many meiotic and postmeiotic gene transcripts are characterized by being structurally distinct from their premeiotic and somatic cell counterparts. The examples in Table 1 illustrate the variety of causes and consequences of this feature. The potential activity of unique RNA-splicing machinery has been postulated on the basis of this information.

2.2.1 Overview of Transcription

Regulation of RNA polymerase II activity in eukaryotic cells is effected by interaction with transcription factors that bind to specific sequences of DNA in each gene. In each cell, the expression level of a particular gene is determined by the nature and abundance of transcription factors at a specific time, and it is common that several factors are influential. Transcription factors are classified on the basis of the predicted structures of their DNA-binding

Tab. 1 Alternative splicing of mRNAs is a feature common to many meiotic and haploid transcripts. This table highlights the diversity of examples.

Protein name	*Known activity*	*Meiotic and/or haploid mRNA splicing features*	*Size [kb]*	
			Somatic or Premeiotic transcript	*Postmeiotic transcript*
c-abl	Cytoplasmic and nuclear tyrosine kinase	3′UTR uses alternative polyadenylation site; no change in protein detected	5.3, 6.5	4.7
c-kit	Receptor tyrosine kinase	Use of alternative splice site; truncated protein encoded lacking all but part of intracellular domain; protein expression not documented (see Sect. 3.4.2)	5.5	3.2, 2.3
CREM	Transcription factor	Protein encoded by spermatocyte mRNA (CREM-τ) has stimulatory rather than inhibitory effect on cAMP-response element (see Sect. 2.2.2)	2 (unique product size detected by PCR)	2
Proenkephalin	Precursor to opiods	Longer 5′UTR; no effect on protein product	1.5	1.9

domains. The common transcription factor motifs are all detected in spermatogenic cells, indicating that the mechanisms employed to effect transcription are conserved between somatic and germ cells. On the other hand, the presence of unique mRNA sizes in spermatids suggests that novel RNA-processing mechanisms exist in the haploid male germ cell.

2.2.2 Transcription Factors

The ubiquitous transcription factor SP1 contains the zinc-finger motif for DNA binding, and it binds to a GC-rich promoter region (GC box) to mediate transcription in genes lacking the TATA box motif. High levels of this protein are present in spermatids. Zinc finger–containing proteins expressed in the testis are encoded on the Y chromosome (*ZFY* in humans and *Zfy-1* and *Zfy*-2 in mouse), on autosomes (*Zfa* in mouse) and on the X chromosome (*ZFX* in human and *Zfx* in mouse). *Zfy-1* expression is first detected in mouse primordial germ cells (PGCs), while *Zfy-2* becomes abundant first between 7 and 14 days of age. Messenger RNA levels in both these increase at the beginning of meiosis. A strain of mouse (*Sxr'*) that lacks the *Zfy-1* and *Zfy-2* genes shows no progression of spermatogenesis into meiosis.

Members of the hormone receptor superfamily also bind to DNA through a zinc-finger domain. Retinoic acid receptor mRNAs are found in Sertoli cells (*Rara*) and (*Rarb)* and in germ cells (*Rara*). Vitamin A deprivation results in blocked proliferation of type A spermatogonia and meiotic prophase entry, while subsequent administration of retinol has been used to produce testes in which all germ cells progress in synchrony through the stages of the seminiferous epithelium.

Homeobox domain and POU domain family members have been detected in the adult testis. Messenger RNAs encoding several OCT proteins have been found in male germ cells at all developmental stages. *Oct-4* gene expression is an important marker of undifferentiated germ cells, as it is present specifically in cells of the embryo epiblast and then in the germ cells that arise from them. In the adult, the *Hox 1.4* gene is expressed in meiotic and haploid germ cells, where its expression may be regulated by retinoic acid.

The leucine zipper family of transcription factors includes *fos* and *jun*, which dimerize to form the AP1 transcription factor that binds to the TPA-response element (TRE). The activity of AP1 varies in cells in response to the activation of protein kinase C, through stimulation by growth factors or phorbol esters. *Jun-D* mRNA is present in all spermatogenic cells, and is predominant in spermatocytes and round spermatids, while the relatively low levels of *c-jun* and *junB* mRNA are highest in type B spermatogonia. *Fra-1* and *c-fos,* and mRNAs are also found in spermatogenic cells. Reversible induction of *c-fos, c-jun* and *junB* transcripts occurs in response to the cell dissociation procedures used to produce purified germ cells for analysis, an important observation for those wishing to study gene expression in purified germ cell populations.

Cellular responses to cAMP levels are mediated through changes in protein kinase A (PKA) activity in order to regulate transcription factors that bind to the cAMP-response element (CRE) in the promoter regions of many genes. Active PKA typically phosphorylates one of the CREB family of bZIP transcription factors, CREB, CREM, or ATF-1 isoforms, enabling its association with a CREB binding protein to affect transcription.

A distinct mechanism of CRE activation occurs in meiotic and postmeiotic germ cells, wherein PKA activation promotes association of CREM with activator of CREM in Testis (ACT), a member of the LIM-only family of transcription factors; this does not involve the activation step *via* phosphorylation required in other cell types. CREs are present in many genes that are specifically or preferentially expressed in the testis or in meiotic germ cells, including those encoding pyruvate dehydrogenase a-2, phosphoglycerate kinase-2, testis angiotensin-converting enzyme, polyubiquitin, transition proteins 1 and 2, protamines 1 and 2, calspermin, and RT-7. In addition, the expression of PKA regulatory and catalytic subunit mRNAs is elevated in meiotic and postmeiotic germ cells, and PKA regulatory subunit isoforms have discrete localizations in the mature human spermatozoan.

The CREB protein exists in a wide range of tissues at low levels, which suggests that its intracellular level is not the primary regulator of its activity, and a modulator protein (CREM) has been characterized (see below). Multiple isoforms of CREB are found in the testis, including those that lack the leucine zipper domain and the nuclear translocation signal; these would presumably regulate the activity of the other isoforms of CREB. CREM also is present in the testis in multiple isoforms. In somatic and premeiotic cells, the presence of CREM α, β, and γ isoforms antagonizes the action of cAMP by downregulating expression of genes bearing the CRE binding motif. Alternative splicing of the *CREM* mRNA in primary spermatocytes produces germ cell–specific forms, designated CREMτ, τ1, and τ2, which act as agonists in round spermatids, where these proteins are found. It is thus apparent from these specific changes in patterns of gene expression in primary spermatocytes that a cascade of changes in intracellular signaling via cAMP occurs. Mice lacking the CREM gene are sterile, with defects evident in round spermatids and a complete absence of elongating spermatids. Expression of CREM and CREB is dependent upon both FSH and androgen, while the switch of CREM from antagonist to activator is effected by FSH. Transcription of CREB appears to undergo positive autoregulation, as its promoter contains three consensus CREs.

Other DNA-binding proteins that are unique to spermatogenesis have been identified using a combination of DNA footprinting, gel-retardation assays, *in vitro* transcription assays, and transgenic mouse production. Promoter regions active in regulating transcription specifically in postmeiotic germ cells were initially identified from regions of homology in the 5'UTR of mouse protamine genes, *Prm-1* and *Prm-2*, which are transcribed only in haploid male germ cells. One of these (region D) confers negative regulation of these genes in somatic cells, while regions B and E appear to confer positive regulatory affects. D element motifs have been identified in the *RT7* promoter, in close proximity to a CREB binding site, where at least one of them appears to positively regulate transcription in nuclear extracts of seminiferous tubules. *RT7* encodes a component of the sperm tail outer dense fiber, also named Odf1, which is required for motility. A 39-kDa protein that is present in nuclear extracts of seminiferous tubules, TTF-D, appears to bind the D_1 element of both *RT7* and *c-mos* promoters. Enhancer and repressor elements have been identified in the germ cell–specific *PGK-2* gene, which appear to coordinately determine the appropriate levels of expression

for somatic and germ cells. Other DNA-binding proteins detected in association with developing germ cells include members of the HMG box (e.g. SRY; see section on Genes controlling testis formation), *ets* proto-oncogene, and *c-abl* families.

2.2.3 Sex Chromosome–encoded Genes

The absence of spermatogonia in the *SRY* transgenic *males* highlights the involvement of other gene products in germ cell development. In as many as 40% of cases of human infertility attributed to the male partner, no specific cause, such as endocrinological failure or presence of antisperm antibodies, can be identified. The concept that other genes required for the successful completion of spermatogenesis are located on the Y chromosome emerged from observations of patients with azoospermia who had small Y chromosomes. Several genes, termed azoospermia factors (AZFs), have been identified in humans by intensive mapping of the Yq11 region of such patients. Deletions in the Y chromosome are highly correlated with a low-to-absent sperm count. ($\leq$1 million sperm per ml).

One group of genes identified at multiple subintervals of Yq11encodes RNA-binding proteins, including DAZ and RBMY. Some of these (e.g. RBMY) appear required for storing and then facilitating translation of mRNAs required for spermiogenesis in elongating spermatids when the genomic DNA has already been packaged with protamine and compacted for long term storage in spermatozoa. New information derived from detailed analysis of the human Y chromosome sequence has indicated that a unique combination of mechanisms are likely to have mediated evolution of genes encoded on the male chromosome. In addition to derivation of genes from common ancestors of the X and Y chromosomes, such as RBMY, the transposition and amplification of autosomal genes (e.g. DAZL, a DAZ paralog) and retrotransposition (CDY) have been implicated.

The X chromosome also harbors genes that are specifically used in male germ cells. Following subtractive hybridization to identify mRNAs expressed in mouse spermatogonia, a disproportionate number of those uniquely expressed in male germ cells (i.e. not in ovary or in other somatic tissues) were subsequently identified as products of X-encoded genes.

2.2.4 Translational Regulation

A predominant feature of gene expression in the testis is the storage of mRNAs synthesized in the meiotic and postmeiotic germ cells for translation at later stages. Relatively high levels of certain proteins are essential at discrete stages of spermiogenesis, such as during tail formation and acrosome development. Accessibility of genes encoding the proteins required for transcription becomes limited during spermiogenesis as nuclear DNA condensation occurs. Transcription has been detected in round spermatids up to stage 8, though translation continues during acrosome and tail formation, finally ceasing with the cytoplasmic rearrangements that precede sloughing of residual cytoplasm prior to spermiation.

There are many mRNAs that are synthesized in meiotic cells but are not translated until later on, in spermiogenesis. For example, an autosomal form of the enzyme phosphoglycerate kinase, PGK-2, is synthesized in spermatids following inactivation of the X chromosome, when the X-linked *PGK-1* gene is no longer transcriptionally active. The *PGK-2* mRNA is synthesized in premeiotic and meiotic

cells but is not associated with ribosomes, and hence not translated until after meiosis. The mRNAs encoding the proteins required for chromatin packaging (transition proteins and protamines), acrosome formation, and sperm-tail structures are also under translational regulation.

Sequences that regulate transcription are present in the 5′ and 3′ UTRs of mRNAs. At the 5′ end, interactions between initiation factors (eIF-4F) and the 5′ cap must occur for translation to begin, and the level of phosphorylation of initiation and elongation factors (which determines their activity) is regulated by extracellular signals. Sequences in the 3′ UTR also influence transcription rates, and the poly(A) tail length of some mRNAs fluctuates in response to signals that mediate changes in their translation rates. Poly(A)-binding proteins (PABPs) increase mRNA stability and hence increase the amount of protein produced, while 3′ AU-rich sequences contribute to the destabilization of mRNAs.

Increased poly(A) tail length correlates with higher levels of association with polyribosomes (and therefore increased translation rates) of some meiotic cell–specific mRNAs, including cytochrome c_T and LDH C, while others show no difference. In contrast, poly(A) tail shortening occurs in association with translation of mRNAs encoding the transition proteins and protamines. These mRNAs are synthesized in round spermatids and stored until spermatid elongation, when they sequentially replace histones during nuclear rearrangement. Premature synthesis of protamine 1 protein in a transgenic mouse caused arrest of spermatid development. Through analysis of *Tpap*-/- mice, a testis-specific cytoplasmic poly(A) polymerase, TPAP, has been identified as essential for progression of round to elongated spermatids. The absence of TPAP is associated with decreased expression of genes required for spermiogenesis, including transition protein 1, protamines 1 and 2, sperm fibrous sheath component 1 (Fsc1), sperm outer dense fiber protein RT7 (Odf1), and heat shock protein Hsc70t. The *Tpap*-/- male mouse phenotype is comparable to that in mice lacking the TATA-binding protein-related factor-2 (TRF2). Analysis of the mRNA-encoding TRF2 and other transcription factors involved in RNA polymerase II-mediated transcription revealed a reduction in the length of the poly(A) tails in the *Tpap*-/- mice, and impairment of transport into the nucleus of the TAF10 protein, all contributing to the reduction in TFIID complex activity required for synthesis of the gene products that are essential for spermiogenesis.

Postmeiotic mRNA translation is mediated by RNA-binding proteins, and several of these have been shown, by gene knockout studies in mice, to be essential for postmitotic germ cell differentiation including Prpb, TLS/FUS, TB-RBP, and SPNR. Testis brain RNA-binding protein (TB-RBP/ translin), present in round spermatids but absent from elongated spermatids, binds specifically to conserved sequences (Y and H elements) in many mRNAs including transition protein 1, protamines 1 and 2, AKAP4, glyceraldehyde 3-phosphate dehydrogenase-S, myelin basic protein, calmodulin kinase II, and tau protein. TB-RBP appears to have a role in storage and transport of these mRNAs, binding them to microtubules and potentially moving these mRNAs between clonal siblings through their intracytoplasmic bridges. It has also been characterized as a DNA-binding protein that may link consensus sequences during recombination and repair during

meiosis in male germ cells and in lymphoid tumors. Spermatid perinuclear RNA-binding protein (SPNR) is also a microtubule-associated RNA-binding protein that is essential for spermatogenesis. The *SPNR* mRNA itself appears to be translationally regulated, as it is synthesized in spermatocytes, and the protein is present only after meiosis. *SPNR*-/- mice produce abnormally shaped sperm in reduced numbers, indicating that SPNR is required for normal completion of spermiogenesis. Phosphorylation of RNA-binding proteins, TLS/FUS, TB-RBP, and MSY2, mediates their dissociation from target mRNAs to enable their translation. The phosphatase that effects this translational activation step in male germ cells has yet to be identified. A potential role for a phosphatase antagonist, the Styx protein, which contains a point mutation in the catalytic domain to render it inactive, is suggested by the phenotype of abnormal and reduced spermatid differentiation and infertility.

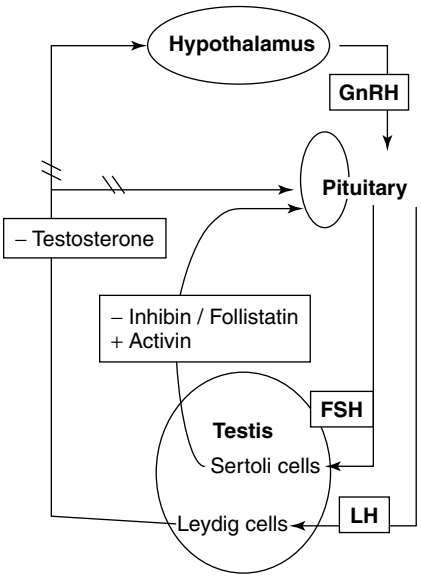


Fig. 4 Illustration of primary components of the feedback loops comprising the hypothalamal–pituitary axis.

3 Control Mechanisms

3.1 Extragonadal and Hormonal Control of Spermatogenesis

3.1.1 Overview

The production of normal sperm numbers in the adult is dependent on the actions of the pituitary gonadotrophins, follicle-stimulating hormone (FSH) and luteinizing hormone (LH). The secretion of these is regulated by gonadotrophin-releasing hormone (GnRH) from the hypothalamus and feedback from the testis *via* testosterone and inhibin (Fig. 4). In the absence of FSH or LH, spermatogenesis is compromised to an extent that varies between species and with the stage of sexual maturity at removal. The receptors for FSH and LH within the testis are present only in the somatic Sertoli cells and Leydig cells, respectively, and hence these hormones affect germ cell development indirectly. The hormone testosterone is also essential for normal spermatogenesis, and its secretion by the Leydig cell is under the influence of LH from the pituitary. Receptors for testosterone (T) are abundant on Sertoli cells, peritubular myoid cells, and Leydig cells. As is true for LH and FSH, the influence of testosterone on spermatogenesis is clearly through the local production of intermediary compounds. In addition, thyroxine has a profound influence on Sertoli cell maturation in immature animals. Recent evidence for the impact of estrogen on testis development has arisen from the analysis of infertile male mice that lack the components of the estrogen synthesis and

signaling pathway; data that reinforce the findings from prior studies that described the impact of estrogen and xenoestrogens.

3.1.2 The Action of FSH and Thyroid Hormone

The action of FSH in the testis is through its impact on Sertoli cell physiology, since receptors for FSH are exclusively located on these cells, while thyroid hormone receptors have been identified in both somatic and germ cells. The impact of these hormones on adult testicular function has been studied using approaches that manipulate their levels and function at defined periods of development and in adulthood. Through recent investigations on humans and mice that are deficient in FSH production and signaling, we now understand that spermatogenesis can proceed in the complete absence of this hormone. These individuals achieve complete spermatogenesis in the lifelong absence of FSH, although the testis size is reduced and fertility is compromised due to suboptimal sperm production and quality.

FSH in the immature testis In immature rats, FSH stimulates Sertoli cell proliferation and the onset of maturation; suppression of FSH levels prior to the normal cessation of Sertoli cell division by day 16 in the rat reduces Sertoli cell numbers in the adult testis. The timing of Sertoli cell proliferation in the juvenile has been established using observation of mitotic figures in histochemical sections and quantitative autoradiography following administration of ^{3}H-thymidine to monitor DNA synthesis. Cell division is evident in the rat fetus at day 16, and the mitotic index of Sertoli cells is maximal between 18 and 21 dpc, corresponding to the period when fetal Leydig cells increase their output of testosterone. The rate of Sertoli cell proliferation decreases after birth and ceases by day 16 in the rat. Thus, the full complement of Sertoli cells in the adult testis is present by this time. It is not known whether Sertoli cell proliferation becomes slower for all cells after birth or whether there exists a discrete population of Sertoli cells that continues to divide until a specific signal to arrest division is received. The response of Sertoli cells to FSH changes during the postnatal period in rats. The initial postnatal period is characterized by being singularly FSH-dependent for proliferation, while between days 5 and 13 postpartum, Sertoli cell proliferation can be transiently stimulated by activin. This effect of activin is augmented by the presence of FSH. Other local factors have been observed to affect Sertoli cell proliferation, including GDNF.

With the termination of mitosis, the Sertoli cell enters a phase of differentiation, wherein continued germ cell differentiation (i.e. onset of meiosis) within the seminiferous epithelium becomes evident, and the lumen of the mature epithelium is formed as Sertoli cells develop tight junctions at the base of the epithelium (forming the blood–testis barrier) and establish a pattern of vectorial secretion. The changed expressions of several mRNAs and proteins are regarded as hallmarks of the now differentiated Sertoli cell, for example, androgen-binding protein.

FSH in the adult testis The impact of FSH in adult spermatogenesis appears to be greatest in regulating spermatogonial development, though its influence on spermatid adherence to the Sertoli cell ectoplasmic specialization has also been documented. However, as stated previously, FSH is not essential for completion of spermatogenesis, but it is required to

achieve quantitatively normal sperm production. In the adult rat, expression of FSH receptor mRNA is greatest at stages IX–XII in the cycle of the seminiferous epithelium, while the protein is apparently most abundant between stages XIII–I.

The impact of FSH on testicular function in the adult varies dramatically between species, with neutralization of FSH having a limited effect on sperm production in rats and a much greater effect in nonhuman primates. Suppression of FSH action has been achieved using passive immunization, injection of high doses of testosterone, and by active immunization against GnRH. In rats, this results in a decrease in testis weight, germ cell numbers, and sperm output of about 10%; in monkeys, a 50% reduction in testis size results from active and passive immunization against FSH. Following hypophysectomy in rats, which removes LH and FSH, germ cell degeneration is most evident at stage VII and can be partially halted by administration of FSH. In this model, in the absence of exogenous testosterone, FSH supports spermatid development to step 8, while the addition of testosterone permits completion of spermiogenesis. This correlates with the finding that androgen receptors are most abundant on stage VII Sertoli cells.

Several *in vitro* studies have documented the effects of the administration or deprivation of FSH on adult rat Sertoli cell protein secretion (e.g. transferrin and inhibin), mRNA synthesis, and cytoskeletal architecture. An increase in spermatogonial and spermatocyte apoptosis, and a reduction in the number of type B spermatogonia entering meiosis is observed in response to FSH withdrawal in adult rats, while administration of FSH increases spermatogonial proliferation and DNA synthesis in spermatogonia and spermatocytes. *In vitro* studies of adult Sertoli cell function indicate that FSH stimulates inhibin secretion both in intact seminiferous tubules and in purified cell preparations. Inhibin will act as a hormone to reduce FSH secretion from the pituitary, but it clearly may have local effects through its impact on TGFβ and activin signaling (see Sect. 3.3.3), thereby affecting germ cell proliferation and differentiation. Some FSH-regulated products are known to act directly on spermatogonia to promote survival, most notably stem cell factor (See section on Interactions between SCF and c-kit affecting spermatogenesis).

Effects of FSH on adult sperm output and quality: *in vivo* and *in vitro* models In the adult rat testis, each Sertoli cell has the capacity to support approximately six to eight round spermatids. Therefore, the potential sperm output of the adult testis (i.e. number of sperm produced per day) is fixed during the postnatal period of Sertoli cell division. Intratesticular administration of an antimitotic drug to reduce neonatal Sertoli cell division resulted in a testis containing a smaller number of germ cells that were present in proportion to number of Sertoli cells at a ratio identical to that in untreated animals.

In addition to the apparent variation in impact of FSH between species, an assessment of the role of FSH on spermatogenesis is complicated by issues such as the purity and source of the FSH administered in older studies, the physiological status of the animal under treatment, and the complexity of intercellular events that occur within the normal testicular environment. With the availability of recombinant FSH for experimental work, and the use of genetically modified mouse models,

a more convincing picture of the interactions between hormones in testicular physiology is developing.

Abrogation of FSH signaling in mice was achieved through the production of mice lacking the genes encoding the FSH β subunit or the FSH receptor. In both these models, spermatogenesis proceeded to completion, but the number of spermatozoa was reduced (to 45–65% of the number in the controls), sperm morphology was abnormal, and fertility was impaired. Similar observations are recorded for patients with homozygous inactivating mutations in the FSH receptor.

Effects of the thyroid hormone on adult sperm output: *in vivo* and *in vitro* models The thyroid hormone receptor is most abundant in rat Sertoli cells during the period when Sertoli cell division is decreasing, between the end of fetal development and the first two weeks after birth. The results of *in vitro* and *in vivo* studies indicate that thyroxine normally decreases Sertoli cell proliferation and promotes Sertoli cell maturation. Thyroid hormone levels affect the cessation of Sertoli cell proliferation. *In vivo* and *in vitro* administration of T3 in rat models promotes premature reduction in Sertoli cell mitosis and the synthesis of products associated with their terminal differentiation. Information from related studies on the influence of thyroid hormone on testicular physiology has reinforced this observation that the Sertoli cell population determines the number of sperm produced in the adult. The induction of neonatal hypothyroidism by administration of prophylthiouracil to the drinking water of pregnant rats and mice results in extension of the period of Sertoli cell proliferation to day 35, with a corresponding delay in their maturation. The extended period of Sertoli cell proliferation results in larger testes in adulthood, with a marked increase in Sertoli and germ cell numbers. Evidence from *in vitro* studies supports the concept that there is synergism between FSH and tri-iodothyronine (T3) in effecting some aspects of this change; thus, the balanced influence of thyroid hormone and FSH actions on Sertoli cell proliferation will have a profound effect on adult male fertility.

3.1.3 The Action of Testosterone

Leydig cell populations and their development The pattern of Leydig cell development varies between species, though the common observation is that Leydig cells are first observed in the interstitium after cord formation. Fetal Leydig cells have been shown to derive from mesenchymal cells originating in the mesonephros under the influence of local factors, including PDGF. Their rapid proliferation is stimulated by chorionic gonadotrophin and LH. This population appears to be static during perinatal life. At the time of puberty, a different population of interstitial cells is stimulated by LH to differentiate into adult-type Leydig cells. It appears that this effect is partly mediated through the actions of FSH. In immature rats, treatment with FSH, but not LH, promoted transformation of interstitial cells into adult Leydig cells, and FSH has also been shown to stimulate both LH receptor activity and T-production in response to LH stimulation. Fetal and adult Leydig cells share the characteristic of containing large amounts of smooth endoplasmic reticulum, and they can also be identified by the presence of steroidogenic enzymes and their capacity to produce androgens. Fetal Leydig cells are easily distinguished by the presence of lipid inclusions, which, in the rat, are mostly absent in the adult Leydig cell.

The abundance of intracellular lipid stores varies in adult Leydig cells with the degree of LH stimulation and availability of dietary cholesterol.

Receptors for LH are found only on Leydig cells, and the addition of LH stimulates production and secretion of testosterone (T). The amount of T produced varies *in vitro* with the addition of various growth factors present *in vivo*, including bFGF, PDGF, and TGFα. Thus, production of T by the Leydig cell is modulated by both local and hormonal signals.

Actions of testosterone The understanding from recent information is that testosterone is required for providing the basal support for spermatogenesis, while FSH affects the quantity and quality of sperm output through its actions in the immature as well as the adult animal.

The presence of testosterone is essential for complete spermatogenesis, though the likely importance of dihydroxytestosterone (DHT) as an alternative ligand for the androgen receptor has been strongly suggested. The binding affinity of the androgen receptor for DHT is 2 to 10 times greater than for T, but T is 5 times more abundant than DHT within the testis and is hence more likely to be available for binding to the receptor. The intratesticular level of T is 50 times greater than what is measured in serum, and the physiological basis for this requirement by the testis of such high levels of T is not known. Androgen-binding protein and albumin in interstitial fluid can both bind T, and may contribute to the two to threefold higher concentrations of T measured in interstitial fluid relative to the testicular venous blood in normal adult rats.

The most profound effects of T on spermatogenesis are exerted at stages VII–VIII of the seminiferous epithelium. Conversion of step 7 spermatids to step 8 spermatids is specifically dependent on T *in vivo*. The absence of T *in vivo* leads to a change in the interaction between Sertoli cells and elongating spermatids. The mature germ cells are not released into the tubule lumen (spermiation), and are instead phagocytosed by the Sertoli cell. Genes encoding CAMs and other components of the ectoplasmic specialization, which mediates attachment of elongating spermatids to Sertoli cells, are regulated by local concentrations of T and FSH.

Restoration of T levels in long-term suppression models leads to rapid restoration of round to elongated spermatid conversion ratios, though the numbers of spermatogonia and spermatocytes are not fully restored. In contrast, the presence of high testosterone levels can inhibit spermatogonial proliferation in models of damaged or recovering testis, such as the *jsd* mouse or the irradiated rat testis, thereby indicating a role for T in facilitating stem cell proliferation or recovery.

While Sertoli cells possess androgen receptors (see above), they may also respond to factors produced by interstitial cells in response to T, to produce the androgen dependency of spermatogenesis. Proteins produced by peritubular myoid cells, such as P-Mod-S, have been implicated in such a scenario, as they stimulate secretion of transferrin, inhibin, and retinol-binding protein by Sertoli cells.

The *hpg* mouse, which bears a naturally occurring deletion of the GnRH gene, has been exploited to elucidate the distinct roles of T and FSH. Administration of T can restore spermatogenic capacity to these animals that are chronically FSH-deficient, in accord with the findings from analyses of FSHβ and FSH receptor knockout animals, though the number of

sperm produced is subnormal. A human FSHβ-subunit transgene was introduced to the *hpg* mouse, resulting in restoration of spermatogonia numbers. Restoration of pachytene spermatocytes to normal and spermatid numbers to near normal numbers was achieved with T administration beginning on day 21 postpartum for 6 weeks. These findings further reinforce the importance of T in the postmitotic differentiation of germ cells.

3.1.4 Estrogen in Spermatogenesis

There is long-standing recognition of the detrimental effects of exogenous estrogen exposure on various aspects of male reproductive tract development and function from the studies of animal models and humans. Fetal and neonatal exposure to estrogenic compounds has been implicated in an increased rate of testicular cancer, cryptorchidism, epididymal abnormalities, and decreased fertility.

In recent years, the influence of estrogens on spermatogenesis has gained a deeper appreciation. Animals lacking the genes encoding the estrogen receptor-α and -β genes (ERαKO and ERβKO mice) and the aromatase cytochrome P450 gene (*CYP19;* ARKO mice) have been generated and examined, and reagents have been developed that can discern the cellular localization of each receptor subunit. The ERαKO mice have impaired fertility due to impaired efferent duct structure and function, while the ERβKO mice are fertile. The ARKO mice suffer from a progressive loss in spermatogenic capacity; the animals are fertile and testicular histology is normal at 14 weeks postpartum, while abnormalities in both the interstitial and seminiferous tubule compartments are apparent after 18 weeks. The double ERKO mice (ER$\alpha\beta$KO) lacking both receptor subunits revealed a phenotype similar to that of the ERαKO, but with distinctively affected mounting behavior.

Because each receptor subunit bears distinct ligand binding and responsive properties, the collection of information about receptor distribution and ligand production is required in order to fully understand the etiology of these phenotypes. Much of this information remains to be sorted out, and there are conflicting results in the literature, some of which are likely to highlight species-specific differences. The ERα appears to be restricted to Leydig and accessory duct cells. ERβ is more widely distributed, found on Leydig and Sertoli cells, in accessory ducts, and in spermatogonia, pachytene spermatocytes, and round spermatids. The aromatase enzyme distribution is similarly broad, having been detected in Leydig and Sertoli cells, pachytene spermatocytes, and in round and elongating spermatids.

3.2 Molecules Involved in Cell Cycle Control

3.2.1 Cyclins

The identification of control points in spermatogenic progression has been achieved by determining cyclin family member expression patterns. Cyclins, proteins originally identified in invertebrate eggs, undergo tremendous changes in levels of expression immediately following fertilization and in subsequent rounds of cell division, with passage through the cell cycle. Individual cyclins have been associated with specific stages of the cell cycle and, to date, at least 8 familes have been identified. Family members are classified as cyclins A through H based on their amino acid homologies and/or their time of appearance during the cell cycle. Cyclin B

associates with a serine/threonine kinase (a cyclin-dependent kinase (Cdk), Cdk1; named $p34^{cdc2}$ kinase in yeast) to form the maturation promoting factor (MPF) which allows the cell to progress through the M-phase of the cell cycle in mitosis and meiosis. The kinase activity of each Cdk is regulated by a complex series of phosphorylation and dephosphorylation events, dependent upon its association with cyclin. Following M-phase, cyclin B is degraded by proteolysis following cross-linking to ubiquitin. This scenario represents the paradigm of how cell cycle passage is regulated, through a sequence of cyclin activation and deactivation events.

Analysis of cyclin gene expression during murine spermatogenesis shows that members of the cyclin A, B, and D families are expressed at discrete sites within the seminiferous epithelium in association with distinct stages of spermatogenic differentiation. There are some differences between reports of their cellular localizations that most likely reflect the nature of the reagent used (i.e. the specificity of the antibody) and the detection method applied. Functional data are predominantly derived from analyses of mice lacking a specific cyclin gene.

The cyclin A family members are usually associated with the G1/S transition of mitotic cells. Cyclin A2 mRNA is present in spermatogonia and preleptotene spermatocytes, and it appears to regulate entry into the meiotic prophase. Cyclin A1 mRNA is synthesized in late pachytene spermatocytes and is essential for the pachytene-to-diplotene transition in mouse spermatocytes. Cyclin B family members participate in the G2/M transition. Cyclin B3 is present in preleptotene and zygotene spermatocytes, and cyclin B2 protein is most abundant in pachytene spermatocytes. Cyclin B1 mRNA is most abundant in round spermatids, although it too is detected in pachytene and more advanced spermatocytes. Cyclin D family members are most abundant in G1 stage cells and are involved with the G1/S transition in many cellular contexts. In the murine testis, cyclin D3 has been observed in gonocytes, round spermatids, Sertoli cells, and Leydig cells. Cyclin D2 expression has been reported as low to negligible, with protein being detected in limited numbers of adult mouse spermatogonia and in Sertoli cells. Its expression in spermatogonia appears to be associated with those cells that are entering the differentiation pathway. The cyclin D2 knockout male mouse testes show a severe loss of germ cells. Cyclin D1, the expression of which is restricted to Sertoli cells, has also been identified as an estrogen–receptor ligand, the significance of which remains to be established.

3.2.2 Cyclin-dependent Kinases and Regulatory Proteins

Cyclin activity is clearly linked to association with a specific Cdk. Cdk4, the binding partner to cyclins D2 and D3, is most highly expressed in the mouse testis during the first spermatogenic wave, predominantly in spermatogonia and Sertoli cells. The absence of this gene in mouse leads to a loss of spermatogonia and spermatocytes. The predominant expression of *Cdc2* and *Cdk2* mRNAs in spermatocytes and their presence in postmeiotic germ cells suggests that these molecules are involved in germ cell differentiation. Other *Cdk* family genes are expressed in adult Sertoli cells, which are nonproliferating, indicating that roles other than cell cycle regulation are played by these kinases.

The cdks that function during G1 of the cell cycle are regulated by specific cyclin-dependent inhibitors (CKIs) belonging to

two families, and many of these functions facilitate rather than inhibit cyclin action. The cip/kip CKIs preferentially affect the action of cyclins A and E through Cdk2. The $p27^{Kip1}$ protein is found in terminally differentiated Sertoli cells, while $p21^{Cip1/Waf1}$ is in pachytene spermatocytes and round spermatids. The INK4 CKIs bind to and inhibit Cdk4 and Cdk6, thereby blocking the activation of the D-type cyclins, the susbsequent phosphorylation of Rb, and the entry into the S-phase of the cell cycle. The INK4 proteins $p18^{Ink4c}$ and $p19^{Ink4d}$ are synthesized in spermatocytes. The absence of either of these genes in mice results in fertile adults with smaller-than-normal testes, increased germ cell apoptosis, and reduced sperm numbers. The combined absence of these two CKIs results in a more severely infertile phenotype in male mice that exhibit delayed entry into meiosis and elevated numbers of spermatocytes undergoing apoptosis. These mice are also characterized by Leydig cell hyperplasia (as seen in the $p18^{Ink4c}$ KO mouse) and elevated FSH. The impact of deregulated cyclin D function, therefore, affects both somatic and germ cells in these animals. This finding may be related to how cyclin D/CDK4 can prevent the inhibitory action of $p27^{Kip1}$ on cyclin E/CDK2. With the loss of CDK4, $p27^{Kip1}$ activity is elevated, and cyclin E/CDK2 function is diminished.

Dephosphorylation of Cdk1 at specific tyrosine residues by the phosphatase *cdc 25* increases its serine/threonine kinase activity to allow progression through mitosis. The expression of *cdc25C* in the adult mouse is highest in the testis, with the germ cells being the predominant site of expression of its mRNA. It is suggested that interactions between Cdc25, Cdk1, and CycB2 in meiotic cells mediate progression through the G2-M transition of meiosis.

3.2.3 Other Regulators of Cell Cycle Progression

The association of a cyclin with a Cdk results in the formation of an active enzyme complex that phosphorylates the retinoblastoma protein (Rb). Rb generally acts to prevent progression through the cell cycle by binding to E2F and blocking its ability to drive transcription. Phosphorylation of Rb leads to its dissociation from E2F, and gene products required for DNA synthesis are then produced. Rb has been detected in Sertoli cells, spermatogonia, and late-stage elongated spermatids in the rat testis, and it undergoes phosphorylation in a cyclic manner through the cycle of the seminiferous epithelium, indicating that its function is regulated during spermatogenesis.

Progression through meiosis depends on the presence of Hsp70.2, a molecular chaperone required for cyclin B/Cdk1 function. Mice lacking Cks2, a mammalian homolog of a yeast Cdk-1 binding protein, enter prophase I of meiosis but fail to complete the first meiotic division (MI), indicating that a specific cyclin–cdk complex is crucial for spermatocyte progression into anaphase. Deletion of the gene encoding the DNA repair protein, Ercc1, affects murine germ cells at all stages of development, leading to the removal of damaged germ cells by apoptosis.

The c-mos protein was originally identified as a component of cytostatic factor with influence during meiosis in testes and ovaries. C-mos regulates progression through the cell cycle at least partly by limiting cyclin degradation. The testis-specific isoform is a 43-kDa protein detected predominantly in spermatocytes. Overexpression of c-mos protein in the pachytene

spermatocytes of transgenic mice resulted in no overt changes in phenotype, including fertility. Overexpression in spermatids resulted in enlargement of testicular size, apparently due to increased numbers of germ cells.

Expression of the pin1 protein has been implicated in enhanced expression of cyclin D1 in several tissues. Its deletion in a mouse knockout model produced a phenotype that was strikingly similar to that of the cyclin D1 knockout mouse in mammary and retinal tissue. However, the testicular phenotype of hypoplasia was similar to that observed in the cyclin D2 knockout mouse, suggesting that pin1 may interact with D2 in the testis.

An understanding of the roles of these and other proteins that interact with the machinery that regulates mitosis and meiosis will reveal much about how hormones and growth factors combine to regulate spermatogenesis. One example is derived from an analysis of mice lacking both *p*27^{Kip1} and *inhibin* α (a member of the transforming growth factor β superfamily; see section on Activin, Inhibin, and Follistatin). The absence of inhibin α leads to development of Sertoli cell and granulosa cell tumors beginning 4 weeks after birth, while those lacking p27^{kip1} have enlarged organs, including testes. Inhibin acts as a *tumor suppressor* in normal tissue by promoting association of p27^{Kip1} with cyclinD2/E1 and Ck4/2, holding them in an inactive complex. In a normal testis, the balance of signals between FSH and inhibin drive Sertoli cell terminal differentiation and exit from the cell cycle, leading to the onset of p27^{Kip1} expression. In the absence of either one of these factors in *p*27^{Kip1}-/-/*inhibin* α-/- mice, this signaling pathway is lost, resulting in the early onset of tumorigenesis.

3.2.4 The Machinery of Meiosis

A plethora of gene products expressed in somatic cells also affect testis development and/or germ cell maturation. The genes that govern the events of meiosis, however, have a unique relevance to the biology of gametogenesis and hence to spermatogenesis. The meiotic prophase begins with DNA replication by the preleptotene spermatocytes. The chromosomes condense and axial elements of the synaptonemal complex are formed during the leptotene stage, followed by pairing of the homologous chromosomes during zygotene. The longest stage of meiosis in the male, pachytene, is characterized by fully aligned, synapsed chromosomes that have undergone the recombination that is required for progression through diplotene (when the chiasmata resolve) and into the successive meiotic divisions, M1 and M2.

Checkpoints to ensure the fidelity of replication and DNA rejoining are key features of meiosis. While some of the crucial genes are known from analysis of infertile mice, others represent mammalian homologs of highly conserved genes that mediate cell division in yeast. DNA mismatch repair proteins, DMC1, COR1, MSH4, MSH5, and MLH1 facilitate formation of the synaptonemal complex that links homologous chromosomes during Meiosis I. The murine Brca1 protein is required for crossing over and repair of DNA damage during spermatogenesis – a function known to be required for suppressing breast tumor formation in humans. The sister chromatid proteins, SCP1, SMC1, and SMC3, facilitate DNA recombination, and the heat shock protein, HSP70-2 mediates disassembly of the synaptonemal complex.

The unique passage of the male germ cell through the G2/MI transition of

Meiosis I has been examined by treating mouse spermatocytes with the protein phosphatase inhibitor, okadaic acid. The pachytene (but not leptotene or zygotene) spermatocyte is competent to proceed through MI all through the several days in which the homologous chromosomes remain fully paired *in vivo*, and the specific machinery required to proceed through the meiotic metaphase is currently being clarified.

3.2.5 Regulation of Apoptosis

It has been estimated that up to 75% of germ cells entering the differentiation pathway will die by apoptosis without completing spermatogenesis. As in the developing ovary, there are waves of germ cell apoptosis in the rodent testis that coincide with the commitment to spermatogenesis by gonocytes and entry of spermatocytes into meiosis during the first wave. This cell death appears related to the need to maintain the optimal numerical ratio of Sertoli to germ cells, to ensure maximal production of fully fertile sperm, while also serving as a quality control mechanism to delete damaged germ cells.

Two pathways for triggering apoptosis are well understood, and both have been identified and characterized within the mammalian testis. The death receptor–mediated pathway is triggered by a signal from one of several extracellular ligands in the tumor necrosis superfamily (e.g. FasL, TNFα) upon binding to a specific cell surface receptor (e.g. Fas, TNFR1). Ligand binding causes receptor trimerization and recruitment of an adaptor protein (e.g. FADD), which leads to association with, and activation of, the central executioner complex of caspase enzymes, initially through activation of caspase 8. The complementary expression of Fas in Leydig and germ cells (quiescent primordial germ cells in the fetus and spermatocytes in the adult) and FasL in Sertoli cells, and of TNFα in spermatocytes and TNFR1 in Sertoli cells, can govern survival of each of these cell types. Treatments causing upregulation of only Fas (radiation, hyperthermia, ischemia/reperfusion) induce germ cell apoptosis, while those increasing Sertoli cell apoptosis (treatment with specific toxicants) induce upregulation of both Fas and FasL.

A separate pathway is triggered in response to a variety of extracellular insults (e.g. irradiation, cytotoxic drugs, serum deprivation) and intracellular events (DNA damage, inappropriate expression of cell cycle regulatory molecules). In this pathway, the balance of prosurvival and pro-apoptotic Bcl-2 family proteins dictates the fate of each cell. In response to injury (e.g. local heating), the upregulation of pro-apoptotic family members leads to cell death. The pro-apoptotic proteins can drive release of cytochrome c from the mitochondrion that, then, binds to Apaf-1, enabling it to oligomerize and recruit procaspase-9. This *apoptosome* now functions to recruit and activate downstream caspases. In both pathways, the end result of caspase activation is degradation of proteins required for maintenance of cell integrity, including nuclear lamins and cytoskeletal elements.

Conflicting reports regarding the cellular localization of Bcl-2 family proteins stem from the limited availability of reliable antibodies; however, it is clear that the expression of these proteins is cell-specific and alters during testis development. For example, while prosurvival *Bcl-2* mRNA is readily detected in spermatogonia and Sertoli cells of the newborn and developing

mouse testis, it is reportedly undetectable in adult testis. Prosurvival Bcl_{XL} and pro-apoptotic Bad are initially synthesized in spermatogonia and Sertoli cells but shift to being synthesized exclusively within spermatocytes as the testis progresses through the first wave of spermatogenesis. Prosurvival Bcl-w and its partner, pro-apoptotic Bax, are present in spermatogonia and Sertoli cells throughout development and adulthood, while the pro-apoptotic Bim is widely distributed.

The functional importance of the balanced expression of the Bcl-2 family proteins has been repeatedly demonstrated though production of transgenic animals that misexpress a prosurvival family member or knockout mice that lack one. In the case of Bcl-2 overexpression in spermatogonia or deletion of Bax, the enhanced survival of germ cells leads to disruption of the seminiferous epithelium about 3 weeks into development, apparently due to the inability of the seminiferous epithelium to function with the excess number of immature germ cells. In the case of Bcl-w deletion, there is a delay in the onset of germ cell death to 3 to 4 weeks postpartum, presumably due to the compensatory function of other prosurvival family members, Bcl-2 and Bcl_{XL}, during the first wave of spermatogenesis.

Expression levels of Bcl-2 family members is probably influenced by the normal milieu of signals that affect testis cells, though to date there are only limited data concerning this point. The levels of bcl-w and bcl-$_{XL}$ in stage VII tubule segments of adult rats are stimulated by *in vitro* exposure to stem cell factor, a known germ cell survival factor normally synthesized by the Sertoli cell under partial regulation by FSH (see section on Stem cell factor). Addition of FSH to these cultures supports germ cell survival through the SCF/c-kit signaling pathway. The rodent testis responds to a variety of insults with changes in apoptotic regulators. Exposure to mild hyperthermia (testicular heating to 43 °C for 15 min) causes redistribution of bax protein from the cytoplasmic to the perinuclear area of the cell within 30 min.

There are conflicting reports describing the effects of testosterone withdrawal by administration of a specific Leydig cell toxicant, ethane dimethylsulfonate, and changes in bcl-2 family members as well as in Fas, have been reported.

The p53 mRNA and protein are found in spermatocytes. A protein with a complex set of functions, inactive p53 is bound in the cell to the heat shock chaperone complex, and when activated, it can regulate expression of bcl-2 and bax to drive apoptosis. Its absence in mice has been reported to impede correct completion of meiotic division l and slightly affect sperm morphology and male fertility. Conflicting reports regarding its functional impact on spermatogenic progression are thought to arise from the differences in the mouse strains examined. Apoptosis of spermatocytes but not spermatogonia appears to be dependent on the presence of p53 in the mouse under normal conditions, whereas the converse has been reported in the case of irradiation-induced DNA damage.

Heat shock factor 1(HSF1) is also bound to the heat shock chaperone complex when inactive. Its release is triggered by various cellular stressors, and the translocation of HSF1 to the nucleus promotes synthesis of heat shock proteins. Similar to p53, HSF1 also appears to have different effects on spermatogonia and spermatocytes, protecting the former and driving apoptosis of the latter in response to heating. Unlike in other cell types, these responses appear to be independent of Hsp70 protein production.

3.3 Growth Factors in Testicular Function

3.3.1 Overview

The term growth factor is loosely applied to molecules that mediate cell proliferation, and yet it is clear that they may instead abrogate proliferation in some circumstances and facilitate differentiation in others. Given the diversity of cell types that are present simultaneously within the testis, it is difficult to distinguish the specific actions of a certain molecule. Highly purified cell preparations and the development of *in vitro* model systems continue to be important for studying the effects of growth factors on testicular cell types. Many examples of potential paracrine and autocrine interactions have been described, and the list of these continues to grow. Many have been detected in more than one cell type, a fact that should inspire caution in investigators as they assess the significance of experimental responses to modulating a growth factor signaling event. Localization and physiological data should also be addressed and interpreted with caution, because of the known artifacts induced by testis cell dissociation and culture. The availability of natural mutants or *genetically engineered* mice with altered expression of growth factors and receptors has provided some information about the roles of growth factors in the testis, but these avenues are limited by the normally diverse biological roles of these same substances outside the testis. Mice with tissue- and cell type-specific ablation of individual genes and the manipulation of immortalized somatic and germ cells *in vitro* are providing new information about local regulation of spermatogenesis.

It is not possible to review the roles of many of the growth factors that are progressively being identified in the testis. The sections that follow will provide an overview of the two growth factor systems in the testis that have been studied with relative intensity.

3.3.2 c-Kit and Stem Cell Factor

The c-kit receptor tyrosine kinase Mutations at the *White-spotting (W)* and *Steel (Sl)* loci in mice can result in animals that are anemic, sterile, and white in coat color. Naturally occurring mutations at these loci have provided a superb source of information concerning two genes that are essential for normal germ cell development. The *W* locus encodes c-kit, a receptor tyrosine kinase glycoprotein in the PDGF receptor family. In humans, the *C-kit* gene covers 20 kb and is comprised of 21 exons. Mutations involving this locus include large deletions, rearrangements and point mutations, and these have been documented in humans, mice and rats. These mutations can affect the amount of c-kit protein expressed and the level of kinase activity; all naturally occurring point mutations described to date are within the kinase domain of the protein. Phenotypic changes accompanying heterozygous mutations affect the melanocyte lineage in humans, but to date no association with human infertility has been documented, nor have homozygous mutations been documented. Dimerization of both ligand and receptor subunits is required for signal transduction, causing autophosphorylation of the c-kit receptor and subsequent recruitment of signaling molecules and activation of Akt by phosphatidylinositol-3 kinase (PI-3K), and of extracellular-signal-related kinases 1/2 (ERK1/2) through SH2 binding proteins including Grb2. This activation drives translocation of cyclin D3 to the nucleus where it effects cellular progression through G1 and into S phase.

Stem cell factor The ligand for c-kit is an integral membrane glycoprotein encoded at the *Sl* locus, and it has been named stem cell factor (SCF; also known as mast cell growth factor (MGF), kit ligand (KL) and steel factor). SCF is encoded by at least 8 exons in mouse, rat and humans. Exon 6 encodes an amino acid sequence that is readily cleaved by proteases on the surface of cells *in vitro*, and this cleavage produces a soluble form of SCF. Two SCF mRNA forms are common to every tissue examined, one including and one excluding exon 6. Differential responses by the c-kit-positive target cell to the soluble and membrane-anchored SCF isoforms have been recorded. The relative proportions of the two SCF mRNA forms changes during testicular maturation, with the membrane-anchored form predominant in early development and the soluble form prevalent in the adult. This alternative splicing is regulated *in vitro* by changing the pH of the culture medium, and it is thought to reflect *in vivo* changes in the local environment as the Sertoli cells mature. Synthesis of SCF is promoted by FSH, and this is a key mechanism by which FSH facilitates spermatogonial survival in the postnatal testis.

Interactions between SCF and c-kit affecting spermatogenesis The involvement of c-kit and SCF in spermatogenesis was originally observed during analyses of *W* and *Sl* mice. Phenotype characteristics shared by mice with mutations in either of these genes reflected a loss of stem cell function in hematopoietic, melanocyte, and germ cell lineages. These mice had varying degrees of anemia, white fur patches, and infertility.

In both *Sl*/*Sl* and *W*/*W* homozygotes, the PGCs form normally and are present in normal numbers until 8.5 dpc, when the number of PGCs declines to about 2% of normal by 12.5 dpc. By 14 dpc, the *Sl*/*Sl* mice are devoid of germ cells, and the PGCs have not migrated from the hindgut to the gonadal ridge, while some migration is seen in the *W*/*W* individuals. *SCF* mRNA is detected in mouse mesodermal cells along the migratory pathway of the PGCs from about 9 dpc and in the genital ridge at 12.5 dpc. Isolated primordial germ cells of mice have been grown in culture with SCF and other growth factors. In these systems, the addition of SCF enhances PGC survival; more limited effects on PGC proliferation and adhesion have been described. In addition, recombinant human leukemia inhibitory factor (LIF) stimulates PGC proliferation *in vitro*, and it is probable that other locally produced factors including BMPs (see sections 'The indifferent gonad' and 'Bone morphogenetic proteins'.) regulate migration, proliferation, and differentiation of these cells.

SCF/c-kit interactions are also essential in postnatal spermatogenesis. Messenger RNA encoding c-kit is found in Leydig cells, differentiating spermatogonia, primary spermatocytes, and round spermatids. C-kit receptor protein has been detected on Leydig cells and spermatogonia, and the postmitotic cell types contain mRNA encoding a truncated protein, tr-kit, consisting of only part of the intracellular domain. Tr-kit accumulates in the postacrosomal region of the sperm head and in the mid-piece of the sperm tail. It is believed to have a role after fertilization in triggering embryo development, as its microinjection into mouse eggs leads to their activation. In contrast to the differentiating type A spermatogonia that have c-kit mRNA and a functional c-kit signaling receptor, stem cell spermatogonia are

characterized by the absence c-kit mRNA and protein. The mechanisms that govern upregulation of c-kit, as these cells become committed to differentiate, are clearly important to identify, and Bmp4 has recently been identified as playing a role (see section on Bone morphogenetic proteins).

Membrane-anchored SCF produced by Sertoli cells can interact with c-kit on spermatogonia, while the cleaved form could reach c-kit on additional distal targets such as interstitial Leydig cells. Binding of murine spermatogonia to Sertoli cells, specifically *via* membrane-anchored SCF interaction with c-kit, has been demonstrated *in vitro*. An antiserum that blocks binding of SCF to c-kit disrupts proliferation of type A_{1-4} spermatogonia *in vivo* and *in vitro*, causing increased apoptosis of spermatogonia and spermatocytes. Genetically modified mice bearing a specific point mutation required for PI-3K-mediated c-kit signaling are infertile due to the specific loss of type A spermatogonia. Abrogation of the PI-3K signaling pathway does not cause the pleiotropic phenotypes of white patches and anemia observed in other *W* locus mutants. These data indicate that Sertoli cell signaling through c-kit is required for survival and may impact on mitotic progression of spermatogonia.

3.3.3 Transforming Growth Factorβ Superfamily

The transforming growth factor, βs (TGFβs), belongs to a family of at least 50 proteins sharing a common dimeric structure that is built upon monomers containing seven conserved cysteines. Two common receptor subtypes with serine/threonine kinase activity are involved in most TGFβ superfamily signaling, type I and type II. The ligands in this family have both distinct and overlapping pathways for signal transduction (Fig. 5). Signaling by each of these many ligands is affected by the local availability of a host of soluble and inhibitory ligands, competition for receptor subunits, and competition from inhibitory and stimulatory intracellular signaling components. Owing to the wide variety of effects of these proteins on a broad spectrum of biological systems, it is clear that their expression and action in the testis will be important in a multiplicity of ways that pose a significant challenge to experimenters. In this section, we will review some aspects of this family of growth factors and receptors that relate to our understanding of their roles in testicular function.

TGFβ Three TGFβ genes have been identified in mammals, encoding TGFβ1–3. These are synthesized as large, inactive glycoproteins that must be cleaved and/or released from binding proteins in order to become activated. TGFβ has an additional type III receptor subunit, betaglycan, a transmembrane proteoglycan with the capacity to bind all three TGFβs that is required to enable TGFβ binding to the type II receptor. Betaglycan is also a coreceptor for inhibin A (see section Activin, Inhibin, and Follistatin). Endoglin is another type III receptor for TGFβs 1 and 3 that can also bind activin A and BMPs 2 and 7.

TGFβ receptors on mouse primordial germ cells may mediate suppression of their proliferation, as has been shown *in vitro* on dissociated cells. Later in fetal development, TGFβ application to cultured rat testis fragments induced apoptosis of gonocytes at the ages when the germ cells were proliferating (13.5 dpc and day 3 postpartum), but not at an age when these cells are quiescent (17.5 dpc). Rat gonocytes possess both type I and type II receptors and synthesize TGFβ3. In the adult rat, TGFβ receptor types are

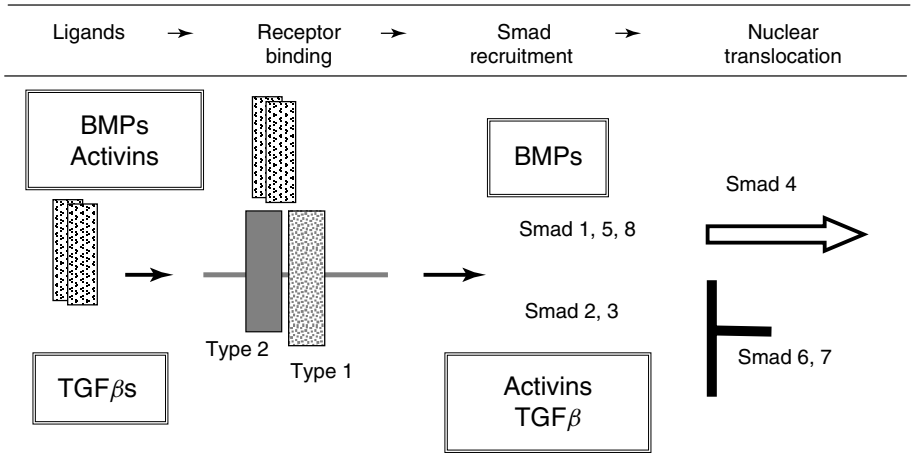

Fig. 5 The TGFβ superfamily members have overlapping and distinct signaling machinery. The local concentration of ligands, inhibitors, receptors, and signaling molecules will create a unique situation in each cell type, with the potential to generate a multiplicity of signals depending on the physiological situation. This diagram illustrates the shared use of receptor subunits by activin and BMPs, while TGFβs use their own set of type I and II receptors and rely on betaglycan for signaling. Inside the cell, activation by activin and TGFβ recruits Smads 2 and 3, while Bmp-signaling recruits Smads 1, 5, and 8. These pathways converge with their requirement for binding the shared Smad 4 to achieve nuclear translocation required for affecting gene transcription, and they are all inhibited by Smads 6 and 7.

coexpressed in pachytene spermatocytes and round spermatids.

Immature Sertoli cells do not appear to have TGFβ receptors, and only the TGFβII receptor has been detected on adult Sertoli cells. However, these cells do make TGFβ1 and 2. Sertoli cell tight junction formation and synthesis of junction-associated proteins *in vitro* is affected by TGFβ3, with *TGFβ2* and *TGFβ3* mRNA levels decreasing as these junctions are being established and increasing thereafter. Secretion of TGFβ2 by Sertoli cells and peritubular cells may relate to how they interact to form the testicular cords *in vivo*, since the addition of exogenous TGFβ2 to cocultures, but not to monocultures, promotes formation of cellular aggregates. TGFβ1 can reduce growth of the embryonic and newborn rat testis, and TGFβ3 has been observed in the cells surrounding the seminferous cords of the early postnatal testis.

TGFβ receptors and ligands are also synthesized in Leydig cells. TGFβ3 immunoreactivity is reported in these cells as early as 16.5 dpc, with functional inhibition of LH-stimulated testosterone synthesis by TGFβ described at day 20.5 postpartum. The *in vitro* regulation of Leydig cell testosterone production by TGFβ1 is at least partially achieved by modulating the numbers of cell surface–LH receptors.

Mullerian inhibiting substance (MIS) At the time of transformation of the indifferent gonad into a testis (see section on Genes controlling testis formation), SRY triggers MIS production in Sertoli cells. Acting through the Bmpr1α receptor located on mesenchymal cells of

the Müllerian ducts, MIS is essential for regression of this duct that contains the precursors of the female uterus, fallopian tube, and upper vagina. At this time, the onset of testosterone secretion by Leydig cells induces differentiation of the Wolffian duct and male external genitalia.

MIS expression is confined to Sertoli cells, with much higher levels measured in fetal and neonatal testes than those observed after Sertoli cell division has ceased. An inactivating mutation in the murine *MIS* gene results in males with normal testis and male reproductive tract development. However, these animals are infertile owing to the presence of Müllerian duct derivatives that present a physical barrier to normal sperm efflux during coitus. This phenotype can be rescued by mating homozygous *MIS* null mice with those that overexpress the human *MIS* gene, thereby demonstrating the conservative structure of the encoded proteins. MIS-deficient females exhibit normal fertility. Foci of Leydig cell hyperplasia were observed in the testes of some (27%) adult MIS-deficient mice, but no other abnormalities were evident in testis weight and growth of seminal vesicles. From results such as these, a role for MIS in regulation of Leydig cell proliferation has been proposed.

Bone morphogenetic proteins Although there is currently limited information concerning the expression and cellular localization of the 15 BMP ligands and BMP receptor subunits, the impact of BMP signaling has been demonstrated at multiple stages in spermatogenesis. Deletion of murine *BMP4* results in the absence of primordial germ cells, as both Bmp4 and Bmp8 signals from the surrounding somatic environment are required for cells to be allocated to this lineage from the embryo epiblast. A potential role for Bmps2 and 4 in governing the fate of murine stem cells has been revealed through the use of *in vitro* treatment followed by transplantation into a recipient host. In contrast to glial-derived neurotropic factor, a distantly related TGFβ superfamily member, the addition of Bmp4 (or activin; see section on Activin, Inhibin, and Follistatin) reduces the stem cell potential of spermatogonia from cryptorchid animals when cultured on a feeder layer prior to transplantation. This suggests that Bmp signaling may provide a signal to differentiate at the onset of the spermatogenic pathway in the postnatal testis. Sertoli cell–derived Bmp4 has been identified as a candidate mediator of the developing mouse testis by upregulating c-kit at this time. Deletion of *Bmp8b* leads to male mouse infertility due to reduced germ cell proliferation at the onset of spermatogenesis and increased spermatocyte loss in the adult testis.

Activin, Inhibin, and Follistatin Inhibin and activin were first identified and purified on the basis of their role in feedback regulation of the testicular–hypothalamic–pituitary axis. The secretion of inhibin by Sertoli cells acts to reduce FSH secretion by the pituitary, while activin has the capacity to stimulate FSH production (Fig. 4). The signaling activity of activin is modified by the binding of other proteins, such as $\alpha_2$macroglobulin, a component of serum, and follistatin. Follistatin is produced within the testis by Sertoli cells under the influence of FSH, and the protein is present in spermatogonia, spermatocytes, and Leydig cells.

Documenting the pattern of activin and inhibin synthesis, the action within the testis is complicated by the fact that they are each dimers, which share a common subunit, with activin being a homo- or

heterodimer of two β subunits (βA, βB, βC, βD, and βE subunits have all been identified), while inhibin is composed of one α and one β subunit (either βA or βB). Inhibin α subunit expression has been detected in Sertoli and Leydig cells, while β subunits have been observed in Sertoli cells, Leydig cells, peritubular myoid cells, gonocytes (βA only), spermatocytes (βB), and round spermatids (βB). The adult Sertoli cell produces predominantly activin B (dimers of βB), while peritubular myoid cells synthesize activin A (βA dimers). *In vivo*, the ratio of α and βB subunits changes during the cycle of the seminiferous epithelium, leading to the suggestion that the relative proportions of inhibin and activin also vary along the length of the tubule. During Sertoli cell maturation, the level of α subunit mRNA synthesis is relatively constant during the proliferative and nonproliferative (maturational) phases, while the α subunit mRNA level decreases as the cells cease to proliferate and begin to mature.

Preferential binding of ^{125}I-labelled inhibin to rat Leydig cells has been reported, and at least two genes have been identified that encode specific inhibin receptor subunits, betaglycan and InhBP/p120. Inhibin, binding to its coreceptor betaglycan (TGFβ type III receptor; see section TGFβ.) blocks activin access to its type II receptor subunit. Betaglycan and InhBP/p120 are both present in Leydig cells. The addition of inhibin to stage dissected–tubule segments in culture results in a decrease in DNA synthesis, specifically in intermediate spermatogonia and in preleptotene spermatocytes, while the addition of activin increases DNA synthesis in the same cell types in this system. This data suggests that either there are other as-yet-unidentified inhibin receptors on germ cells, or that inhibin blocks activin signaling by direct competition for activin receptor binding sites. The effect of activin βA addition on immature rat Sertoli cells is to stimulate their proliferation during a discrete window of postnatal life. Activin addition to Sertoli cell cultures also regulates androgen receptor expression and FSH-induced aromatase activity.

Messenger RNAs encoding activin receptor subunits have been detected in Sertoli and germ cells at all stages of maturation, with stage-dependent peaks during the cycle of the seminiferous epithelium in the adult. Activin, like TGFβ1, inhibits proliferation of mouse primordial germ cells in culture. In contrast, activin increases gonocyte numbers in cultures of testis fragments taken from the newborn rat testis, while blocking their differentiation into spermatogonia at the onset of spermatogenesis. This differentiation was stimulated by the combined addition of FSH and follistatin. Other studies with mouse tissues have shown that activin, like BMP, reduces the stem cell potential of germ cells in culture. The addition of activin to cocultures of Sertoli and germ cells leads to increased spermatogonial proliferation and cellular aggregation. Hence activin may play a role in regulating the proliferation or differentiation of germ cells at many stages of development, further demonstrating the intricacy of regulation, which must contribute to achievement and maintenance of normal spermatogenesis. Messenger RNA encoding a membrane-bound inhibitor of TGFβ superfamily signaling, Bambi, is upregulated as germ cells transform into spermatogonia at the onset of spermatogenesis. In the adult, Bambi mRNA appears highly expressed in pachytene spermatocytes and round spermatids, making it another potential player in the complex set

of interactions that govern regulation of TGFβ signaling in the testis.

Another role of activin in the testis may be to maintain the immunosuppressed nature of the interstitium. Activin has been shown to suppress proliferation of peripheral T lymphocytes, an activity that would limit the influence of lymphocytes when presented with novel antigens such as haploid germ cell products, as might occur during testicular damage.

Our understanding of how inhibin and activin act are regulated within the testis is incomplete. In a genetically engineered mouse lacking the inhibin α subunit gene, no effect on testicular development or adult fertility was observed, suggesting that the physiological role of inhibin is either limited or at least partially met by another protein. However, the subsequent development of stromal cell tumors indicates that inhibin can function as a tumor suppressor (see Sect. 3.2.3). Disruption of the *βB subunit* gene has no affect on male fertility, but it has a profound influence on female fecundity manifested as perinatal lethality in offspring of homozygous females. The βA-/- mouse dies at birth, so the importance of the βA protein on postnatal development cannot be studied in these animals. Insertion of the βB gene into the βA locus has been performed to create mice with reduced activin bioactivity (activin A is reportedly 10-fold more bioactive than activin B in terms of signaling), and the animals survive to adulthood. The males are fertile but exhibit a delay in completion of the first wave of spermatogenesis. This further highlights the importance of activin A in the first wave of spermatogenesis, correlating with downregulation of this mRNA during the first week of postnatal life. *In vitro* studies and detailed mRNA analyses conducted on newborn rats has shown that the quiescent gonocytes synthesize activinA in the fetal testis, and the protein is stored until the cells transform into spermatogonia. At this time, the germ cells begin to synthesize the activin antagonists, follistatin and Bambi, indicating that the commencement of their differentiation requires a downregulation of activin signaling.

4 Conclusion

It is clear that a complicated set of hormones and locally produced factors determines the pathway of testis development and spermatogenesis. It is a challenge for the future to further develop model systems that will allow germ and somatic cell differentiation to proceed *in vitro* and to use the techniques that allow manipulation of gene expression in discrete cell types *in vivo*. Already the potential exists, with the production of immortalized somatic and germ cell lines which can support some degree of progression through meiosis. Advances in germ cell and organ transplantation have enabled sperm development in the testis of a host. We are just learning how to identify, store, culture, and stimulate the development of spermatogonial stem cells. This new information is being applied to better understand the source of the complex regulatory signals that guide spermatogenesis, to identify contraceptive targets, to understand the genetic basis of male infertility, and to restore fertility in genetically deficient individuals.

Keywords

Cell Cloning
Generation of a colony from a single cell. Subculturing results in a cell strain.

Cell Cycle
Ordered sequences (G_1, S, G_2, and M) of cellular syntheses between two cell divisions.

Cell Line
Subcultured primary cultures. A cell line can be finite or continuous.

Cell Strain
Cell line that has been purified by physical separation, selection, or cell cloning.

Continuous Cell Line
Indefinite proliferation. This immortalization of a cell line may be induced by a viral gene transfer or was already acquired by some cancer cells before cultivation.

Primary Culture
Freshly isolated cells in culture until the first passage into a subculture.

Serum
Blood fluid without cells and clotting factors.

Suspension Culture
Cells proliferate isolated from each other when suspended in growth medium.

Tissue Culture
Accustomed term for the cultivation of animal cells. Originally: Fragments of tissues maintained *in vitro*.

Mammalian cell cultures originate from tissue explants or cell suspensions as primary cell cultures that can be subcultured with a limited life span. By transformation, these cells might lose some of their original properties and establish permanent growth. Many of these continuous cell lines are aneuploid and genetically unstable, nevertheless, our knowledge of molecular, physiological, biochemical, and biophysical properties of cells is notably based on investigations with such cell lines. Since the synthesis of various bioproducts such as vaccines, monoclonal antibodies, enzymes, and hormones is accomplished with cell cultures, many efforts were made to develop and improve cell culture technology. Besides this impetus, cancer research also stimulated the progress of cell culture methods as can be seen with the development of three-dimensionally growing cultures. These cultures provided a better understanding of tumor invasion and revealed the importance of the extracellular matrix for physiological regulations of cell–cell interactions that

cannot be observed with monolayer or suspension cultures. This knowledge helped to improve the cultivation of cells that are used in clinical treatments as is the case for wound healing with implantation of epidermis or for defect organs such as liver, which can be supported with bioartificial organs during a temporary extracorporal bypass.

1 Principles

1.1 Development of Cultured Cells

Animals are three-dimensionally organized complex multicellular creations. Their tissues and organs maintain specific internal milieus and are separated from each other and from their environment by specialized endothelial and epithelial cells. The adult human body consists of hundreds of cell types and altogether of approximately 50 to 100 $\times$ 10^{12} cells from which about 10^9 cells vanish within one hour. This sounds more alarming than it really is because most of these cells are replaced within the same time. The highest turnover is found for blood and epithelial cells; after wounding, organs and tissues might start proliferation albeit they are normally almost quiescent. Even when most cells have the potential for proliferation, it is not an easy task to cultivate them *in vitro*, that is, in Petri dishes, flasks, or bioreactors.

A stimulus to study isolated cells was given in 1858 when Rudolf Virchow postulated that pathological characteristics may be detected on a cellular level. First experiments to cultivate cells were performed with non-mammalian cells such as amphibians with their high capacity to regenerate lost limbs and with chicken embryos that are easily accessed and proliferate with a high activity. Successful attempts to maintain cells *in vitro* date back to 1885 when Wilhelm Roux kept isolated nerve fibers of chicken embryos alive in a warm saltbroth. Much effort was put in the establishment of an appropriate medium in which the cells could survive and even proliferate. In 1895, Paul Ehrlich succeeded to grow and propagate mouse tumor cells by intraperitoneal injection in mice where they grew as single-cell suspension in ascites. This *in vivo* cultivation revealed that the liquid of the peritoneum obviously contains all nutrients necessary for cell proliferation. Consequently, human ascites was used to keep pieces of human skin alive *in vitro*, as was demonstrated in 1898 by Ljunggren who grafted them back to the donors, including himself. A significant step forward was achieved in 1907 by Ross Harrison, who cultivated spinal cords of frogs in a hanging drop of coagulated frog's lymph and studied the outgrowth of nerve fibers during several weeks. In 1912, Carrel reported on the permanent life of tissues outside the organism when he cultivated embryonic chicken cells in an extract of chicken embryos. He introduced aseptic methods and cultivated the cells as monolayers in glass flasks, but that he has kept these cells for more than 30 years is certainly not true since *in vitro* proliferation of normal cells is limited to about 50 divisions, which became known

later by the investigations of Hayflick and Moorhead. Carrel and coworkers had regularly fed their cultures with insufficiently filtered extracts of chicken embryos, which contained fresh cells.

Different media were adopted for specific cells, which grew as monolayers on different substrata such as glass, polypropylene, ceramics, and so on. Earle and coworkers treated mouse fibroblasts with methylcholanthrene and cultured these transformed cells in medium with a bicarbonate/CO_2 buffered salt solution. These L-cells have been growing as a continuous cell line since 1943, and at present their use might only be outnumbered by the first continuous human cell line HeLa, which was derived from a human cervical carcinoma by Gey and coworkers in 1952 (Fig. 1). Modified medium formulations were used by Dulbecco to grow animal viruses in cultured cells and Eagle described in 1955 the minimum requirements of nutrients for appropriate synthetic media, which, however, still required the addition of serum from young animals. Another important step was made by Levi-Montalcini and colleagues who isolated of a protein, which stimulates the growth of certain nerve cells. Similarly, to this nerve growth factor, other growth factors were later isolated from serum (see Sect. 2.2). With better-defined media, more complex cells could be cultivated as was the case with the successful development of a hybridoma cell line for the production of monoclonal antibodies by Köhler and Milstein.

Even from the very beginning of tissue culture, three-dimensional explants were always used, and most experiments are still performed with monolayer and suspension cultures. This might change in the near future since many regulatory processes are better studied in three-dimensionally growing cells that perfectly match the *in vivo* conditions.

1.2 Selection of Cells

Most animal cells are cultivated as monolayers since the majority of cells is anchorage dependent and not very selective with regard to a substratum. This type of cell cultivation offers advantages for microscopic inspections during growth or during experiments and it allows micromanipulation of the cells with electrodes. Normal cells in a primary culture usually stop proliferation by a so-called contact inhibition when they come in close contact on a flat surface. By serum deprivation, the proliferation of these cells can also be inhibited and they remain quiescent in the G_1- or G_0-phase

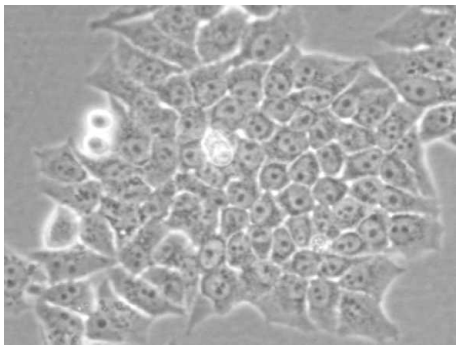

Fig. 1 Monolayer of HeLa cells during logarithmic growth. Diameter of a cell is about 15 µm. Light-microscope phase contrast picture.

of their cell cycle. After addition of serum to these cultures, the cells reenter the cell cycle and progress in a synchronized manner. Under these conditions, signals from individual cells are multiplied since effects occur synchronously in all cells as has been demonstrated for growth factor–induced channel openings in embryonic rat fibroblasts. In spite of the high variance of samples, cells of primary cultures are recommended when specialized functions should be investigated under controlled culture conditions.

Cultures with selected properties are available with transformed cells. They are not contact inhibited and continue to grow as long as the medium is not depleted of nutrients. Numerous investigations in cell biology as well as in cancer research were performed with these continuous cell lines and cell strains, and much of our knowledge on cellular regulation, synthesis, and proliferation is based on these cells. For the production of cellular material, cells were selected after transformation, hybridization, or transfection. In catalogs of the American Type Culture Collection (ATCC), of the European Collection of Cell Cultures (ECACC), or of other national culture collections, appropriate cells for many purposes can be found.

Since production is usually optimized for a high yield, cells were further selected for anchorage-independent growth, which qualifies them to proliferate and to synthesize the requested product in single-cell suspension in large volumes. However, as is evident from intact organisms, producer cells must not necessarily be in a proliferative status. This understanding finally led to cultivation methods that allow the cells to grow as three-dimensional cell aggregates. This might end in organ-like cultures where the cells stop to proliferate but still synthesize substances or function as bioartificial organs as is the case for extracorporal cultivated liver cells.

1.3 Cell Cycle and Growth Curves

Under optimal conditions in culture, cells may divide every 10 to 20 hours except when cells may be stressed by transferring from one culture vessel into the next or by exhausted medium. Between two cell divisions, a cell must synthesize all its materials such as DNA, RNA, proteins, lipids, and so on. These processes could occur continuously or in discrete phases. As has been demonstrated by Quastler and Sherman, DNA is replicated in a separate phase that starts a few hours after division and ends a few hours before the next division. This DNA synthesizing period is called *S-phase*, it is preceded by the G_1- and followed by the G_2-phase, whereas the M-phase covers the mitosis and the cell segregation between the two G-phases. Similarly, as in an adult organism, cells may stop proliferation and rest in the G_0-phase.

When cells are cultivated as suspension culture, they exist as isolated single cells and can easily be harvested without enzymatic treatment and transferred directly into a new culture vessel. Under these conditions, cells may immediately continue to proliferate at a high rate. During mitosis, one cell divides into two cells and, therefore, the number of cells increases to $N + 1$. Since one ''old'' cell disappears after its doubling time and two ''young'' cells are instead added to the culture, we must distinguish between growth rate $G = (dN/dt)$, which indicates how many cells are added to a culture during a certain time period, and the birth rate

$B = 2G$, which gives the number of cells that are "born" at a certain time point. A culture of continuously proliferating cells has, therefore, twice as much young cells as old cells and its age distribution declines exponentially.

Under these conditions, an exponential growth is observed, which is described by

$$N = N_0 \cdot e^{\mu \cdot t} \qquad (1)$$

with N: number of cells; N_0: number of cells at the start of the culture; growth parameter $\mu = ln2/t_d$; t: time; t_d: doubling time of cells. Every cell has an individual cell age τ that starts after mitosis at $\tau = 0$ and ends at $\tau = t_d$ with the next division. Under optimal conditions, the individual doubling time of a cell could be identical with the population doubling time. However, during growth, the medium will gradually be exhausted and some cells may stop proliferating or are prolonged in their cell cycle because one or more restriction points cannot be passed. Furthermore, when monolayer cells are transferred from one vessel into the next by trypsinization and mechanical treatment, they might additionally be stressed by temperature shifts and their proliferation in the new vessel starts delayed. These delays result in characteristic growth curves as is shown in Fig. 2 for BICR/M1R$_k$ cells. For fitting these points with a curve, the growth parameter μ must be modified to $\mu = \mu_1 - \mu_2 N$ and leads to the Verhulst–Pearl equation:

$$N = \frac{\mu_1 \cdot N_0 \cdot e^{\mu_1 \cdot t}}{\mu_1 + \mu_2 \cdot N_0 (e^{\mu_1 \cdot t} - 1)} \qquad (2)$$

This equation represents realistic growth conditions in which the proliferation also depends on the number of cells and the available amount of nutrients in a medium. A typical growth curve starts with a lag-phase in which the number of cells is rather constant before the cells start with exponential growth and enter the log-phase. For practical reasons, the ordinate of a growth curve is logarithmically divided and, therefore, the log-phase is characterized by a straight line. When the medium is deprived of nutrients, cells stop proliferating and for a while the number of cells is constant – the culture is in its stationary phase before cells start to die away.

1.4 Cell Profiling

Altogether, several ten thousands of cell lines may be kept worldwide; therefore, a reliable identification of the cells becomes mandatory. Besides microbial contamination and phenotypic drift, cross-contamination between cells occurs more

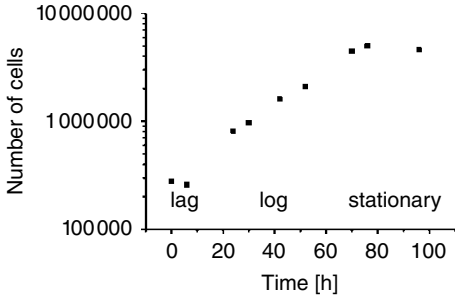

Fig. 2 Growth curve of BICR/M1R$_k$ cells with a typical lag-, log-, and stationary-phase. This continuous cell line originates from a mammary carcinoma of the Marshall rat.

often than it is detected and leads to severe misidentifications of cell cultures. Within 10 years of the start in culture of the human cancer cells HeLa, other human and animal cell lines were contaminated with these fast-growing HeLa cells as was detected by genetic markers. These alarming reports did not stop this carelessness and in 1976, Nelson-Rees and Flandermeyer reported more than 90 cell lines that were contaminated with HeLa cells. It is still estimated that up to one-third of all cell lines is of different origin or species to that claimed. These cross-contaminations result from careless handling as might be the case when several cell lines are transferred simultaneously and medium is added to all cultures with the same pipette. Aerosols and small droplets with cells might adhere to the outside of the pipette and are thus transferred into the stock medium from where they can contaminate other cultures. Cross-contamination could be detected by experienced molecular biology laboratories with several time-consuming and expensive methods, but none was suitable for use as an international reference standard. With the development of new PCR-based forensic techniques, an inexpensive method, the short tandem repeat (STR) profiling, has been applied to DNA from human cell lines. STR generates standard numerical codes for lengths of polymorphic DNA loci, which qualify as universal reference standard for human cell lines. Masters and colleagues recommend DNA profiling of cell lines as a normal practice and suggest this analysis as a prerequisite for publication. This DNA fingerprint will not only help to identify cell lines and greatly enhance the confidence in these studies but should also allow comparisons of published results on a more solid basis as momentarily possible.

1.5 Ethical Rules

Working with continuous cell cultures does not seem to cause severe ethical problems; however, when primary cells are acquired from humans and animals, several critical implications arise. For clinical treatments as well as for research, the use of human stem cells from embryos, fetuses, or adults is strictly regulated by national and international legislation. However, research with other human cellular material must also be justified and can only be approved by local research ethical committees when the demands of national guidelines are enforced. Similarly, the use of animal tissue requires ethical and legal approval, often by local animal welfare committees. Animal welfare aspects include the minimizing of pain, suffering, distress, and lasting harm as well as the restriction to the absolutely necessary number of animals. Experiments with cultures of permanently growing cells do not exclude animal welfare considerations since most cell lines are still maintained with purchased fetal bovine or newborn calf serum. Even when little or no influence can be taken on the collecting process, there are also technical arguments for considering a replacement of serum (see Sect. 2.2).

2 Techniques

2.1 Preparation of Primary and Continuous Cultures

A primary culture starts with biopsies from solid tissues or organs, preferentially from embryos, but tumor cells are

also often selected because of their high proliferation capacity. These firmly attached cells have to be disaggregated to single cells, a procedure that combines mechanical dissociation and enzymatic detachment. After chopping the tissue with fine surgical scalpels, proteolytic enzymes such as trypsin, collagenase, or pronase are applied to open proteinaceous bonds between cells, a process that might be accelerated by the appropriate temperature and thorough pipetting. This cell suspension will be diluted with medium plus serum; centrifuged and resuspended in medium for several times before the cells are transferred into Petri dishes or flasks. Most cells are anchorage dependent and will adhere to an appropriate substratum after a few hours. At that time point, the cultures must be washed free of all cellular debris and damaged cells, since only a small portion of cells may have survived the isolation procedure. Microscopic inspection will then reveal the yield of attached single cells, but also aggregates of cells will be found from which an outgrowth of cells can be observed after a couple of days. Usually, a mixture of cell types will be present in these primary cultures, the majority being fibroblasts that will proliferate better than other cell types. Since they are also motile, they can grow out from cell aggregates and spread over the substratum. Epithelial cells, on the other hand, are more or less immobile and tend to form patches on the substratum. Figure 3 shows a primary culture of embryonic mouse brain cells in which nerve cells have spread on top of other cells that are out of focus.

Adherent cells can be detached by trypsin, and enough cells might be harvested from these primary cultures to proceed with their propagation in multiple dishes or flasks. These subcultures can be used to multiply the selected cells and generate a new cell line that contains all the different cells of the primary culture. If these cells are selected from normal tissues, these cultures have a limited life span and must, therefore, be multiplied by several cultivation passages, collected, and stored in liquid nitrogen so that planned experiments can always rely on identical cell populations (see Sect. 2.5). Critical cells may not proliferate, especially when the density of transferred cells is too low. This problem can sometimes be solved either with conditioned medium or with feeder layers. The so-called conditioned medium is taken from a culture of logarithmically growing cells and added to freshly propagated cells. This medium contains cell specific factors that mimic the presence of numerous cells and stimulate the growth of critical cells. A similar effect can be obtained with irradiated feeder layer cells, which form a monolayer and serve as substratum for critical cells.

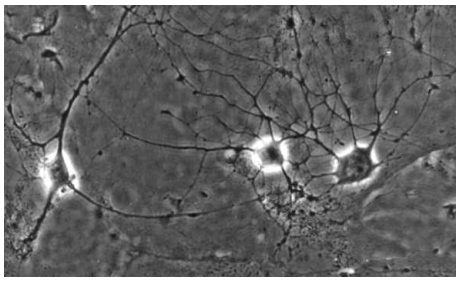

Fig. 3 Primary culture of embryonic mouse brain cells. Nerve cells have spread on top of other cells, which are out of focus. Light-microscope phase contrast picture.

By transforming and cloning cell lines, permanently growing cell strains with specific properties can be derived, and many of them are available from cell banks. A majority of experiments is, therefore, performed with these continuous cells.

2.1.1 Monolayer Cultures

Plasma membranes of animal cells carry fixed negative charges that allow cell–cell adhesion by divalent cations (Ca^{++}, Mg^{++}), but cells may also adhere to artificial surfaces that are either negatively or positively charged. Cells form a monolayer when they adhere not only to each other but also to the surface of culture vessels. Different cells form differently arranged monolayers: epithelial cells (Fig. 1) show a typical cobble stone appearance, whereas transformed fibroblasts (Fig. 4) may grow criss-cross and pile up when a high density is reached. The cells' morphology might indicate that the medium is exhausted and its replacement or a subculture is necessary. For propagating the cells, the medium is withdrawn and trypsin is added with a Ca^{++}/Mg^{++} free balanced salt solution. The time and temperature required for this treatment depend on the sensitivity of the cells, and other enzymes might also be required for a gentle disaggregation. In any case, the enzymatic treatment should be as short as possible to avoid unnecessary stress. Therefore, the cells must be washed with medium to block the activity of trypsin by its serum. The cells can then be detached from the surface by repetitive pipetting of medium over the monolayer, a procedure that also disperses floating cell aggregates. Portions of this resulting single-cell suspension are used for subcultures, and an aliquot might be used for determining the concentration of cells. The number of cells that are necessary for starting a new culture depends on the cell type, on the kind of planned experiments, and on the type of culture vessels. A few hours after starting the incubation of new cultures, they can be microscopically inspected to exclude any damage that might have occurred during the passage.

2.1.2 Suspension Cultures

Several monolayer cell lines have lost their anchorage dependence by transformation and are now also kept as suspension cultures. HeLa cells are amongst these cultures, which grow as monolayers and in suspension. Primary suspension cultures can be obtained from normal lymphocytes, which are anchorage independent. They have a limited life span, but lymphoblastoid cells with unlimited growth in culture are also available as are other ascites tumor cells that have lost their anchorage dependence already *in vivo*.

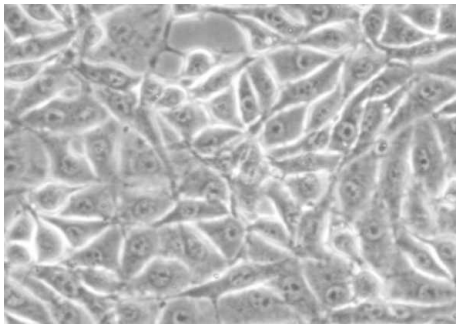

Fig. 4 Monolayer of BICR/M1R_k cells during logarithmic growth. Light-microscope phase contrast picture.

2.1.3 Three-dimensionally Growing Cultures

Not only may primary explants grow three-dimensionally but also transformed cells can be cultured as so-called multicellular spheroids in suspension. For a few anchorage-dependent cell lines, it is sufficient to start a culture of these cells in a stirrer flask for suspension cultures. When cells meet each other in this suspension, they will stay together and thus form larger spheroidal aggregates within a couple of weeks. Most other cell lines must first be kept in dishes with a nonadhesive surface to induce this three-dimensional growth. These Petri dishes are commercially available and are mainly used for cultivating bacteria on agar. After a few days of cultivation in these dishes, the cells have formed irregular aggregates, which are transferred into stirrer flasks in which they form multicellular spheroids and may be kept and treated for several weeks (Fig. 5). Spheroids can be harvested directly with pipettes, and medium is easily replaced since the spheroids precipitate quickly when they are no longer stirred. When such a spheroid is placed on a culture dish, the cells quickly adhere to this charged surface and within a day many cells will have migrated from the spheroid and proliferate again as monolayer cells.

When biopsies of organs are cultured in stirrer flasks, they will maintain morphological and physiological properties, and many cells remain fully differentiated and proliferate sparsely. Even when fresh explants are required for new experiments, these cultures offer some advantages for complex experiments that might, for instance, include immunological reactions as has been shown with lymphoid tissue and HIV infection.

Epithelium, which separates an organism from its environment or an organ from its surrounding fluid, is formed by layers of different cells. When cultured *in vitro*, epithelial cells often form flat monolayers of different cells but epidermal cells may be kept as organotypic flat multilayers in a liquid–gas interphase. This *in vitro* skin is another example for the many types of three-dimensionally growing cultures that are not only used to study tissue regeneration but are also applied in biomedical treatments.

2.2 Cell Culture Media

The basic components of cell culture media are inorganic salts, glucose, and organic substances, which are also present in blood plasma of animals. Their concentration varies with different compositions of

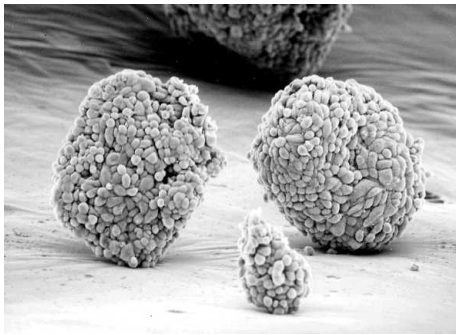

Fig. 5 Multicell spheroids of BICR/M1R$_k$ cells. The diameter of the larger spheroids is about 350 µm. Scanning electron microscope picture.

media that were designed for specific cells with special properties. Most of these media are commercially available as solutions and also as powder that has to be dissolved in water. The selection of water, however, is not trivial since it may contain organic and inorganic material, which will not be removed by simple distillation so that other purification processes must be included. Differences in cell activity may be due to different water qualities; therefore, the use of ultrapure water is recommended. In any case, powdered media require sterilization by filtration through a pore size of 0.22 μm, preferably during bottling and before storage in a refrigerator.

All basic salt broths of cell culture media contain NaCl, KCl, $CaCl_2$, and $MgCl_2$. The concentration of these inorganic salts is set to adjust the osmotic balance of the cells and maintain their membrane potential. When this solution is buffered to a pH value of 7.2 to 7.4 with the pH buffering phosphates NaH_2PO_4 and Na_2HPO_4, it can be used to keep the cells alive for a short while. A complete medium requires much more additives for the functioning of inorganic salts as mediators for cell attachment or as enzyme cofactors. Carbohydrates (glucose) are added as energy source, and amino acids serve as nitrogen sources, although glutamine can also provide a carbon source via transamination. Essential and nonessential amino acids and water-soluble vitamins are also necessary as nutrients and additional energy sources; their concentrations vary with different medium formulations.

For proliferating mammalian cells, the buffering capacity of the medium is increased by bicarbonate ($NaHCO_3$). In this case, the medium's CO_2/HCO_3 content must be balanced by gaseous CO_2, which requires gassed incubators in which an atmosphere of 5–10% CO_2 in air can be maintained. Another buffering system is given by the zwitterion HEPES, which is often used together with the "natural" bicarbonate buffering system. With this buffer, cells can be manipulated under atmospheric conditions without drastic pH changes. For a rapid and easy control of the medium's pH, phenol red is added as indicator.

Many laboratories supplement their medium with antibiotics such as streptomycin sulfate and penicillin G. This reduces the risk of bacterial contamination but increases the development of resistant organisms and encourages the use of inadequate aseptic techniques. Transfected cells, however, may have been selected as resistant to puromycin or geneticin, and the use of these antibiotics is recommended for maintaining a selection pressure.

A very important component of a cell culture medium is serum, and in most cases newborn calf or fetal bovine serum is added. Serum is a complex mixture that contains not only essential growth factors but also plasma proteins, hormones, metabolites, and growth inhibitors. Since serum components are affected by age, health, and nutrition of the donor animals, the quality of serum will change from batch to batch and, therefore, every new batch has to be tested for the required quality standards. When bovine spongiform encephalopathy (BSE) spread in cattle, guidelines became effective, which should minimize the risk of BSE transmission via medicinal products and the necessity for media without any material from animal origin has increased.

At the beginning, the so-called serum-free media contained factors that were isolated from serum and stimulated the

growth of certain cell types, which can be seen from their name: fibroblast growth factor (FGF), nerve growth factor (NGF), epithelial growth factor (EGF), platelet-derived growth factor (PDGF), and insulin-like growth factor (IGF). Other serum-isolated additives include interferons, hormones, and attachment factors. With these components, a serum-free medium was still an undefined medium since it contained components that were subject to variation. Effects to develop defined media where the chemical structure and the concentration of every component are known were successful. These media are consistent from batch to batch and are optimized for growth of specific cell types and product synthesis. Almost every cell line requires its own expensive serum-free medium, its use is therefore still limited to productions with expensive purification processes and to some biomedical treatments.

2.3 Equipment

2.3.1 Vessels

Monolayer cells need a substratum to adhere, and this material must be of good optical quality since microscopic inspection of the cells is mandatory for most experiments, but other material might be advantageous when it comes to production. Cells preferentially adhere to negatively charged surfaces and, therefore, the plastic vessels for cell culturing are charged during the manufacturing process. Many laboratories use transparent disposable multiwell plates, Petri dishes, and T-flasks made of polystyrene. Their volume varies between 0.1 and 250 mL medium and with the corresponding surface areas. However, other mechanisms are also effective in cell adhesion. When cells are cultivated on glass surfaces, they might not adhere well when the glass flasks are first in use. After several passages of cells, the adhesion is enhanced, indicating a conditioning of these glass surfaces. This is due to specific receptors for cellular adhesion, which are part of the extracellular matrix of plasma membranes. They partly remain adherent to the glass surfaces when the cells move or are harvested. Even after cleaning and sterilizing, material is firmly connected with the glass and thus facilitates the attachment of cells of sequential cultures. This finally led to the use of special mixtures of extracellular matrix glycoproteins and proteoglycans by which any substratum could be made available for the cultivation of critical cells. Continuous cell lines such as HeLa adhere to different substrata, for example, carbon-coated glass (Fig. 6) and polished stainless steel (Fig. 7).

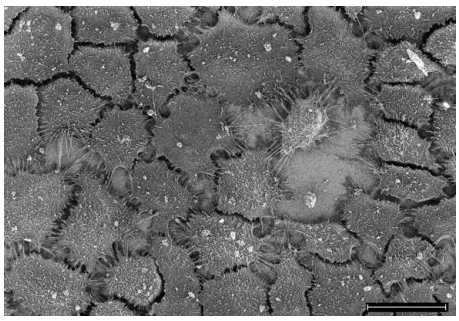

Fig. 6 Monolayer of HeLa cells during logarithmic growth on carbon- coated glass. Attached particles originate from serum and/or dead cells' debris. Scanning electron microscope picture, bar = 30 µm.

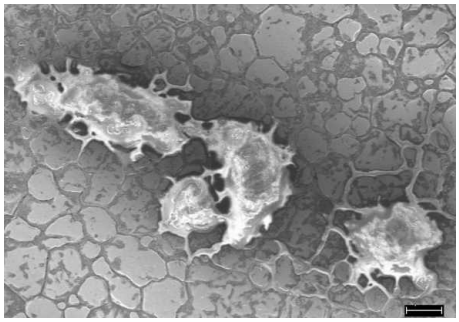

Fig. 7 HeLa cells grown on stainless steel. Note the amoeboid protrusions onto the nonpolished gaps. Scanning electron microscope picture, bar = 10 μm.

Many sophisticated systems have been developed to improve the yield of monolayer cells. Since the area of the substratum on which the cells can grow must be increased and the volume of the vessels must be expanded, risks of contamination and problems of regulation will also simultaneously rise. These tasks are solved with different strategies. A classical technique is the use of cylindrical bottles that are slowly rotated so that the total inner glass or plastic surface is available for cultivating monolayers with a small amount of medium. Many of these roller culture bottles can be rotated simultaneously on racks and thus increase the total amount of products. Other mass culture techniques make use of separated compartments in which the cells grow on permeable membranes and medium is provided in a compartment separate from the products, a strategy that reduces the cost of product purification. An example is the hollow fiber, which is not only used for adherent but also for suspended cells. The surface of substratum can also be increased when the cells are grown on microcarriers. These small beads with diameters of about 200 μm are fabricated from different materials, such as polystyrene, silica, glass, or dextran and may be coated with collagen or mixtures of cell adhesive substances. Cells can grow as monolayers on these beads, which are kept as suspension and thus mediate mass cultivation of monolayer cells.

Cells can also grow isolated in suspension cultures in which they must be kept floating with a minimum of shear stress and optimal conditions for growth and production. For small volumes, this is achieved with stirrer flasks or gyratory shakers, but cells may also be cultivated in air-lift bioreactors that may hold several ten thousand liters. In small stirrer flasks, the medium is kept in motion with magnetic stirrers and rotating paddles or pendulums, necessary controls are maintained by the incubator's devices. This is no longer possible when the volume of a stirrer flask exceeds one liter. Scaling-up in volume requires better controls of medium conditions; therefore, bioreactors are equipped with sensors for the regulation of gas, temperature, pH, and metabolites.

To prevent outgrowth of cells, multicellular spheroids and three-dimensionally growing biopsies are constantly kept in motion in stirrer flasks or gyratory shakers. For this cultivation in small volumes, an interesting alternative is given by rotating wall vessels that were designed for cell growth in low or zero gravity. Their rotation speed is so adjusted that the cells remain stationary, which not

only facilitates the formation of three-dimensional aggregates but also explants from organs and tissues can be maintained under these conditions.

2.3.2 Appliances

Essential equipments that are used in tissue culture laboratories are shortly mentioned here. A laminar flow hood protects not only cells from microbial infections but also the operator from hazardous materials (see Sect. 2.4). Incubators must allow regulation of temperature, CO_2, and humidity and provide good internal convection. An autoclave is necessary for sterilizing solutions, but medium must be filtered since many ingredients will not tolerate the high temperature in an autoclave. Wasted dishes and other disposable material that came in contact with pathogens or with cultures of primate or transfected cells must also be autoclaved before they are trashed. Glassware and glass pipettes can be sterilized in a dry heat at temperatures higher than 160 °C for at least one h. Besides refrigerators and freezers for storing substances and solutions, liquid nitrogen canisters should also be available for deep-freezing and storing cell lines. Ultrapure water might not always be necessary, but a cell culture laboratory should have access to a supply; in any case, deionized and distilled water must be available. Well-adjusted phase contrast microscopes, both upright and inverted, are important tools in a cell culture laboratory since microscopical inspection of the cells during growth and before an experiment can save time and costs when inappropriate cells are to be used. A balance should not be missing as well as centrifuges and many other helpful instruments such as pH meter, cell counter, dispensers, pipettors, and a glassware washing machine.

2.4 Safety and Biohazards

For any workplace, national regulations are effective that prevent operators from safety hazards of physical or chemical origin. Working in a tissue culture laboratory adds further sources of potential safety hazards, which originate from cell cultures contaminated with latent viruses or occult pathological organisms. A known risk comes from transfected cells for which not only the origin of the cell line but also the transfection vector outlines the risk. A low individual and community risk is given with microorganisms that are unlikely to cause disease in healthy operators or animals and with cell lines that are not of human or primate origin. These risk group I agents can be handled in a containment level I laboratory that matches a functionally designed standard microbiology laboratory. Aseptic techniques must be used and all liquid waste should be treated with bleach or similar detergents. Since during pipetting aerosols are formed that might carry cells and unidentified pathogens, it is good laboratory practice to protect operators with a laminar flow hood with an air barrier at the front opening and an exhaust filter.

Agents that are of moderate individual and limited community risk are classified as risk group II. This includes cultures of primate and human origin, recombinants, transfectants, and animal tumor cells. A separate containment level II laboratory with separate equipments is obligatory, and cells must be handled in a class II laminar-flow hood. Human cell lines that are virus-producing or are infected with pathogens have a high individual and a low community risk and are classified as risk group III. These cells can also be handled in a class II laminar-flow hood,

but any waste and material that came in contact with cells must be sterilized before leaving the separate containment level III laboratory. Only designated laboratory staff is allowed to work in this room.

The risk group IV is given when a high individual and a high community risk must be expected from the experiments. This includes human pathogens that produce very serious human or animal diseases that might be untreatable and readily transmitted. Biopsies and cell cultures carrying known human pathogens must be handled in a containment level IV laboratory. In addition to the requirements for a level III laboratory, this laboratory must be physically isolated and functionally independent of other areas and must have an air lock for entry and exit. Class III biological safety cabinets and/or positive pressure ventilated suits protect designed operators for whom a shower and change of clothes are obligatory when entering or leaving the laboratory. Authorization for handling transfected cells and human pathogens as well as the routine inspection of containment laboratories are regulated by national laws.

2.5 Storage

Primary cells have a limited life span and continuous cell lines may change properties by transformation, dedifferentiation, or because of genetic instability and infection. When production or research depend on certain properties, it is therefore essential to have a stock of cells with the original properties. Cell lines as well as small multicellular organisms and embryos can be preserved by freezing since much of the cellular volume is water that is essential for cellular metabolism. When water becomes to ice, cellular metabolism is stopped and cells can be kept for years under cryopreserved conditions when the temperature is deep enough.

Before freezing, cells should be maintained under routine conditions and must be inspected for contamination. Monolayer cells are harvested during exponential growth by trypsinization; suspension cultures are concentrated by centrifugation. Cells must be thoroughly washed and resuspended to a concentration of about 1 to 10 million cells per milliliter freezing medium. This freezing medium is composed of the appropriate growth medium plus a high concentration of serum (50% or more) plus dimethyl sulfoxide or glycerol. This cell suspension is transferred in plastic ampoules wherein cells will be frozen at a slow rate till they reach $-70\,^{\circ}C$ and will be kept overnight before they are transferred into liquid nitrogen and stored at $-196\,^{\circ}C$.

For thawing, an ampoule is placed in a $37\,^{\circ}C$ water bath and slowly agitated. Its content is transferred into a flask and diluted with medium. After 6 to 8 h, when viable cells are firmly attached, medium with dead cells and cellular debris should be aspirated and fresh medium is added.

3 Applications

Considerable knowledge of cellular structures and functions is the result of investigations with cells in culture. This includes intracellular synthesis processes for numerous macromolecules, such as nucleic acids and proteins, as well as for most other relevant cellular molecules. Intracellular energy and signal transfer, cytoskeletal architecture, transport through membranes, product formation, but also cell–cell interactions, malignant transformations, and

microbial infections are representatively mentioned for the numerous issues for which answers were found in cell cultures. A few examples for applications in research and production are given that concentrate on the importance of three-dimensionally grown cell aggregates, a method that might become the standard technique in the future.

3.1 Cellular Regulations

Complex cell interactions and epithelial differentiation were studied with organotypic cocultures of flat epidermal multilayers and revealed the normal regulation and balance of these cells. For this *in vitro* epidermalization, a collagen matrix at the basal side is required, whereas the keratinocytes are exposed to air. The collagen layer also supports dermal fibroblasts that synthesize the right extracellular matrix proteins. Together with the metabolites of the medium, which is separated from the collagen layer by a filter, all necessary components are available for proliferation and differentiation of the epidermal cells.

Intracellular regulations are not only dependent on the combination of cells but also on the culture conditions. This is trivial as long as necessary metabolites or messenger molecules are missing or are too low in concentration; however, with the same concentrations available in medium, cells may behave in a completely different manner when grown three-dimensionally as cell aggregates instead of as two-dimensional monolayers. An example is the so-called contact effect, which was observed for multicellular spheroids in which the tumor cells are more sensitive to irradiation than in two-dimensional growth. Later, it was detected that cells that were coupled to their neighbors via gap junction channels showed this effect more pronounced. Gap junction channels regulate an intercellular exchange of ions and molecules of up to 900 dalton and are normally found to be open in monolayer cells. However, in multicellular spheroids of several tumor cell lines, the permeability of these channels will be regulated, they were found open in two-day old spheroids and were closed two days later. It is still unknown what controls this channel closing, but channels may open again when the cells were allowed to grow as monolayer. Another growth-dependent regulation was demonstrated with β-galactosidase synthesizing L-cells. For this production, the cells had been transfected with a lacZ gene, which was under control of a β-actin promoter. This constitutive transfection led to a constant production when the cells were cultured as monolayer but β-galactosidase activity was downregulated in cells that were cultivated as spheroids. Since monolayer L-cells are motile, a permanent synthesis of cytoskeletal elements such as β-actin is required, but in spheroids the cells are rather immobile and the synthesis of β-actin is downregulated, which also effects the β-galactosidase activity. In contrast to the layered growth of epidermal cells, multicellular spheroids contain only one type of continuously growing cells, and these are exposed to gradients of metabolites, protons, and oxygen. Furthermore, spheroids establish an extracellular matrix, which is not found when the same cells are cultivated as monolayers.

3.2 Cancer Research

Malignant growth of cells can only be understood correctly when the modes for normal growth are known. Both cases can be

investigated under the same experimental conditions with cell cultures. A successful model for studying carcinogenesis *in vitro* is again the multilayered epidermis, which allowed examination of malignant transformation and tumor progression. A problem of metastatic behavior of tumor cells is invasion, it can be investigated *in vitro* with cocultures of three-dimensionally grown aggregates of normal and malignant cells. First, attempts were made with organ cultures from chick embryo or fragments of human endometrium, which were confronted with suspended tumor cells. When precultured embryonic chicken heart fragments were confronted with tumor cell spheroids, invasive behavior could be analyzed with immuno-histological techniques, and comparative studies revealed that this *in vitro* invasiveness matched the *in vivo* situation. Interestingly, it was shown that invasive tumor cells were coupled to the host via gap junction channels and that noncoupled HeLa cells became invasive after transfection with a connexin gene, which led to an expression of host-compatible gap junction channels. Several other prerequisites for invasion have been detected with similar cell culture models: Metalloproteases were found to be active during invasive processes of tumors from brain and the cell adhesion molecule e-cadherin plays a role when breast tumor cells invade the host. Weakening the cadherin-mediated cell–cell contacts facilitates detachment and migration of single tumor cells in a mesenchymal type of movement. Recent studies with new fluorescent probes allowed a time-resolved investigation of invasive processes in three-dimensional collagen matrices and revealed a supramolecular plasticity mechanism with a transition from a proteolytic mesenchymal toward a nonproteolytic amoeboid movement.

3.3 Production

Two modes of cellular production are possible: either the product remains within the cells or it is secreted into the medium. In any case, purification processes are necessary and, therefore, the culture conditions should be adjusted and optimized to increase the yield and avoid unnecessary costs. For biomedical treatments, the cells are often the requested product, which requires safe culture conditions. These should not only perfectly match the host's physiological conditions but must also be free of nonhuman additives that may be due to limited cleaning processes.

Monoclonal antibodies are produced by hybridoma cells in suspension culture. They are secreted into the medium and can be harvested with the culture supernatant. For mass production, hybridomas are often grown in hollow-fiber cultures that facilitates harvesting; the highest yield, however, might be achieved when hybridomas are grown as ascites culture in mice.

Amongst the first products of monolayer cultures were therapeutically important substances such as viral vaccines and tissue plasminogen activator, which were harvested from roller bottle cultures or from microcarriers in suspension cultures. With the availability of genetically manipulated cells, the production of therapeutically relevant proteins with animal cell cultures increased considerably. The list of these substances encloses insulin, interferon, interleukin, plasminogen activators, blood clotting factors, hemopoietic growth factors, hormones, vaccine, and so on. Many of these proteins have a complex tertiary structure and require posttranslational modifications that can only be synthesized in animal cells but not in bacteria. For mass production, producing cells

are often additionally modified so that they tolerate high shear stress when cultivated as suspension in large bioreactors.

An often-applied method in biomedical treatment is transplantation of skin. For this purpose, small pieces of skin will be taken from the patient, cut, and expanded to a mesh. They will then be cultivated, and keratinocytes will fill the interstice. These pieces can then be retransplanted onto the wounds of the patient. Another approach, which is still under development, is the temporary support of defect organs such as liver by bioartificial organs via an extracorporal bypass.

4 Perspectives

Biomedical treatment with primary or continuous cell cultures requires complex growth conditions, and some of the current approaches might lead to new therapeutic applications. Three-dimensionally growing cells do not completely represent the cells' behavior in human or animal, and monolayer cells are not necessarily representative for more complex culture systems. This does not argue against investigations with cell cultures as long as possible limitations are taken into account.

A great potential of research with monolayer cultures is given by certain cellular functions such as channel activities, intracellular transport, or protein synthesis. Examples are cells that were transfected with a fusion construct that leads to the synthesis of proteins that are labeled with a fluorescent protein. This labeling enables investigations of supramolecular dynamics by microscopic techniques such as internal reflection fluorescence or fluorescence correlation spectroscopy. Results obtained with these techniques offer insights into general cellular transport and diffusion processes.

Cellular production has been optimized with selected cell types that grow under adequate suspension- or monolayer-conditions and might still be expanded with other transfected cells and new recipes for synthetic media. A great potential for production can be expected from cell cultures of coelenterates and arthropods because pathogens are unlikely to transfer to human cells. Successful cultivation of three-dimensional aggregates of sponges has already been reported, and continuously growing insect cells are available for a longer time.

Keywords

Abductive Inference or Abduction
Inference to the best explanation as proposed by Charles S. Peirce.

Collision Induced Dissociation or MS/MS
In CID, a selected precursor ion is activated by collisions with neutral gas molecules and fragmented into daughter ions.

Electrospray Ionization
A method for the ionization of nonvolatile molecules such as proteins, peptides, sugars, and nucleic acids by spraying the sample solution onto a small orifice in the mass spectrometer.

Endopeptidase
An enzyme that cleaves a polypeptide chain of proteins at a specific site.

Genome
The complete DNA sequence of an organism.

Mass Spectrometry/Mass Spectrometer
In mass spectrometry, a mass spectrometer measures the mass of almost any molecule that can be ionized in the gas phase.

Matrix-Assisted Laser Desorption/Ionization
A method for the ionization of nonvolatile molecules such as proteins, peptides, sugars, and nucleic acids by irradiating the mixed crystals between sample molecules and laser dye (matrix) molecules in the mass spectrometer.

Peptide Mass Fingerprinting
Identification of a protein through the measurement of the masses of endoprotease-cleaved fragments in reference to genome information.

Post Source Decay
The fragmentation of ions after the acceleration in the ion source prior to entering the reflectron that separates the daughter ions.

Posttranslational Modification
Covalent modification of amino acids in proteins taking place during and after the translational process.

Proteome
The full complement of proteins produced by a particular genome.

Proteomics
The study of the full complement of proteins encoded by a genome.

Two-dimensional Gel Electrophoresis
A gel electrophoresis system to separate a complex mixture of proteins by an isoelectric focusing in the first dimension followed by the sodium dodecylsulfate polyacrylamide gel electrophoresis in the second dimension.

U
The symbol for a mass unit representing one-twelfth the mass of carbon; equivalent to dalton (Da) used in biochemistry.

The completion of genome projects represents a pinnacle of human enterprise in the biosciences. The orchestration of technologies in mass spectrometry, genome science, and computer sciences has created a new branch of molecular bioscience called proteomics. A proteomics approach to the study of protein expression and posttranslational modification does not require foreknowledge of the identity of target proteins. A proteomic investigation begins with the discovery of unidentified proteins of interest under well-defined physiological conditions. The approach involves (1) protein display by 2-D gel electrophoresis or other separation technique; (2) determination of protein entities of interest; (3) peptide mass fingerprinting (PMF); and (4) genome/proteome database search. The methodology of the proteomics approach is characterized neither by *deduction* nor by *induction* in the traditional sense, but is a clear example of what C. S. Peirce described as *abductive inference* a century ago. *The investigation of molecular and cellular events is often intractable to deductive and inductive methods due to its extreme complexity and nonlinearity*. Proteomics is a powerful tool to study complex biological systems because of its characteristics: (1) no *a priori* knowledge of the protein's identity is required to initiate a project; and (2) a holistic approach is possible for investigation. It is expected that proteomics will substantially contribute to the future development of molecular medicine.

1 Proteomics: the Primary Application of Mass Spectrometry to Biomolecules

In the last decade, mass spectrometry, which has longer than a century of history in physical sciences, entered a new era: two new ionization methods that enable mass measurement of nonvolatile biomolecules such as proteins, nucleic acids, and sugars have been invented and perfected. The new types of mass spectrometry, together

with the development of genome science, opened up a totally new type of inquiry into the molecular aspects of life. ''Proteomics'' represents such emerging genre of molecular biosciences that utilizes biomolecular mass spectrometry and genome information.

1.1 What is Proteomics?

Proteomics is a new discipline in biosciences, which aims to study the proteome. The new term ''proteome'' was first used in late 1994 at the Siena 2-D Electrophoresis Meeting and was first printed in a scientific journal in 1995 by Wasinger et al. There is an inherent relationship between genome and proteome and the creation of the former precedes the latter. Therefore it would be appropriate to briefly explain genome before defining proteome. The term genome was first used around 1965 to represent the whole set of information encoded by chromosomal DNA. Some of the early literature includes the following: Mauer (1965), Breeze and Cohen (1965), Winocour (1965), Diamandopoulos and Enders (1965), Easton and Hiatt (1965), and Heisenberg and Blessing (1965). Since each species of living organism possesses a particular set of chromosomal DNA, it can be said that each living species possesses one genome. Moreover, since the chromosomal DNA remains the same in every cell under any physiological conditions within a certain species, the genome also remains the same. The usage of the term genome implies that each species possesses only one genome, that is, human genome, rat genome, *Drosophila* genome, yeast genome, *Escherichia coli* genome, rice genome, and so on. Those terms are well defined scientifically although there could exist some variations in genome even among the same species. In contrast to the well-defined nature of ''genome'' by itself, ''proteome'' needs to be defined with caution. The first usage of the term proteome is as follows: ''proteome'' refers to the total complement of a genome or the complement able to be encoded by a given genome. Thus, the term proteome was coined about three decades after the term genome was introduced. The MEDLINE (OVID) entries of relevant manuscripts reflect this historical fact: a search with ''genome'' yields more than 7800 entries, whereas the search for ''proteome'' yields about 1700 entries as of late 2002. The early literature that used the word ''proteome'' include Wasinger et al. (1995), Kahn (1995), Wilkins et al. (1996a), Yan et al. (1996), Qi et al. (1996), O'Brien (1996), Wilkins et al. (1996b), Wilkins et al. (1996c), Shevchenko et al. (1996), Celis et al. (1996), Wimmer et al. (1996), and Wilkins et al. (1996d). In their 1995 paper, Wasinger et al. carefully added that it is unlikely that the totality of this potential for protein expression will be realized at any one given instant. According to the ''central dogma'' of gene expression, DNA encodes mRNAs, and the mRNAs encode proteins. In the past half a century, since the establishment of the double helix model of DNA and its replication, many modes of molecular mechanisms that affect and regulate the expression of proteins have been discovered. The entire process of protein expression consists of three distinguished steps: transcription, translation, and posttranslation. Every process that affects any of these steps modulates the ability of the genome to express itself, thereby modulating the proteome. Under a certain condition a certain type of cell expresses a group of proteins that is a subset of the total complement of a given genome. Because changes in physiological

parameters even in the same type of cells most likely affect protein expression transcriptionally, translationally, and/or posttranslationally, the kinds and amounts of proteins expressed under one set of physiological parameters will be different from those under another set of physiological parameters. Thus, in contrast to genome, which is a rather static entity under all physiological conditions, the proteome is a dynamic entity: there is only one genome for a given species, but there are many realizations of proteomes even for the same single species. This characteristic of the proteome makes it essential to define precisely the samples for proteome analysis because without defining the biological parameters such as cell types and physiological conditions the interpretation of the proteome analysis will be ambiguous. In a certain sense, all the traditional experiments performed on protein targets can be called ''proteomics studies.'' However, there appear to be intrinsic differences between the traditional experimental inquiries in biochemistry and molecular biology and those of proteomics studies in two ways: (1) proteomics renders high throughput of inquiries because of the advance in technology of protein separation and analysis by mass spectrometry and genome database, and (2) the advent of technology to investigate proteins on a massive scale has enabled us to utilize a type of investigational logic, which is distinct from the traditional biochemical inquiries. A new logical inference appropriate for proteomics will be discussed in the following Sect. 3.1 Proteomics and Abductive Inference.

In contrast to the static aspect of genome, the dynamic aspect of genome will be studied by a new area of discipline called ''functional genomics.'' In functional genomics, the expressed mRNAs will be studied under a well-defined condition compared to a control. The pool of mRNAs will be reverse-transcribed into cDNAs and the resulting cDNAs will be analyzed mainly by a DNA array technique. In the interpretation of DNA array experiments, the amount of a protein and that of the corresponding mRNA are assumed to be correlated, which is not always the case, at least in the case of monocellular eukaryote yeast. Further studies need to be performed to evaluate the studies of mRNA expression in reference to the protein expression, especially in higher eukaryotes. In order to achieve this goal, a sensitive and reliable methodology for quantitative proteomics of expressed proteins will be essential. (See Sect. 5 Quantitative Proteomics.)

2 Technical Basis of Proteomics

2.1 Protein Display for Proteomic Investigation

The early proteomic inquiries can be found in works in which a mixture of proteins were separated by 2-D gel electrophoresis. Although there had been several precedents for 2-D gel systems before O'Farrell (1975) invented the modern and powerful method of separating a mixture of proteins, the O'Farrell-type 2-D gel system has been proven to be a powerful method for the separation of a complex mixture of proteins. O'Farrell's protocol combines isoelectric focusing (IEF) gel under a nonionic detergent NP-40 and urea in the first dimension and the traditional Laemmli-type sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) in the second dimension. Almost at the same time, Ames and Nikaido reported a similar 2-D gel system that

makes the use of sodium dodecyl sulfate (SDS) possible for solubilizing membrane proteins. Since O'Farrell's protocol does not solubilize many of the intrinsic membrane proteins in the sample, Ames and Nikaido's method complements that of O'Farrell's. Early work using 2-D gel electrophoresis clearly demonstrated that protein expression and posttranslational modification *in vivo* are dynamic processes (for example, see Lee et al., 1979; Giometti and Anderson, 1981; Willard and Anderson, 1981; Kosik et al., 1982; Neukirchen et al., 1982; Matsumoto et al., 1982; Matsumoto and Pak, 1984). Although these examples and others indicated the power of 2-D gel electrophoresis for studying the protein expression, its weakness is that the researchers at that time did not have the power to identify the proteins of interest. This identification of proteins of interest would have to wait another decade for the development of new technologies. In the 1980s, many new and powerful technologies in biochemistry and molecular biology were developed. Modern biotechniques relevant to early proteomic inquiries include monoclonal antibody production, membrane blotting techniques both of nucleic acids and proteins, gas phase Edman degradation performed on the membrane blot, and cDNA cloning techniques including $\lambda gt11$-based protein expression vectors that enable library screening using antibodies. It should be noted that in the 1980 to early 1990 genome databases did not exist. Therefore, cloning of each gene encoding the protein of interest was the only way to identify the gene. The premise of proteomics is that as long as a protein of interest is distinctively displayed by a 2-D gel or other methods, one can identify the protein and its gene without gene cloning. This capability of proteomics approach gives us an opportunity to catalog all the genes expressed in a particular tissue such as, for example, retina; see Fig. 1.

2.2 Mass Spectrometry: an Essential Tool for Proteomics

In late 1980s, two important ionization methods were invented and revolutionized the modern mass spectrometry: Koichi Tanaka invented matrix-assisted laser desorption/ionization (MALDI) and John Fenn invented electrospray ionization (ESI), for which both scientists received Nobel Prize in Chemistry in 2002 (http://www.nobel.se/chemistry/laureates/2002/). Before the invention of ESI and MALDI, the analyte molecules had to be volatile for any mass spectroscopic analysis. Biopolymers such as proteins, peptides, nucleic acids such as DNA and RNA, and polysaccharides cannot be analyzed by traditional mass spectrometers unless they are chemically modified to render them volatile. This is not always possible except for some shorter polymers.

A mass spectrometer consists of three important components: (1) the ion source that ionizes the analyte molecules (for example, MALDI and ESI are two types of ion sources that can ionize nonvolatile molecules such as proteins, peptides, and nucleic acids); (2) the ion analyzer that separates each ion from the mixture according to the mass-to-charge ratio (m/z); and (3) the detector that counts the number of ions characterized by a specific m/z value. Several types of ion analyzers are currently available: for example, magnetic sector–type ion analyzer, quadrupole (Q) ion analyzer, time-of-flight (TOF) ion analyzer, quadrupole ion-trap (QIT) ion analyzer, and Fourier transform ion cyclotron resonance (FTICR) ion analyzer. Theoretically, any combination of ion source

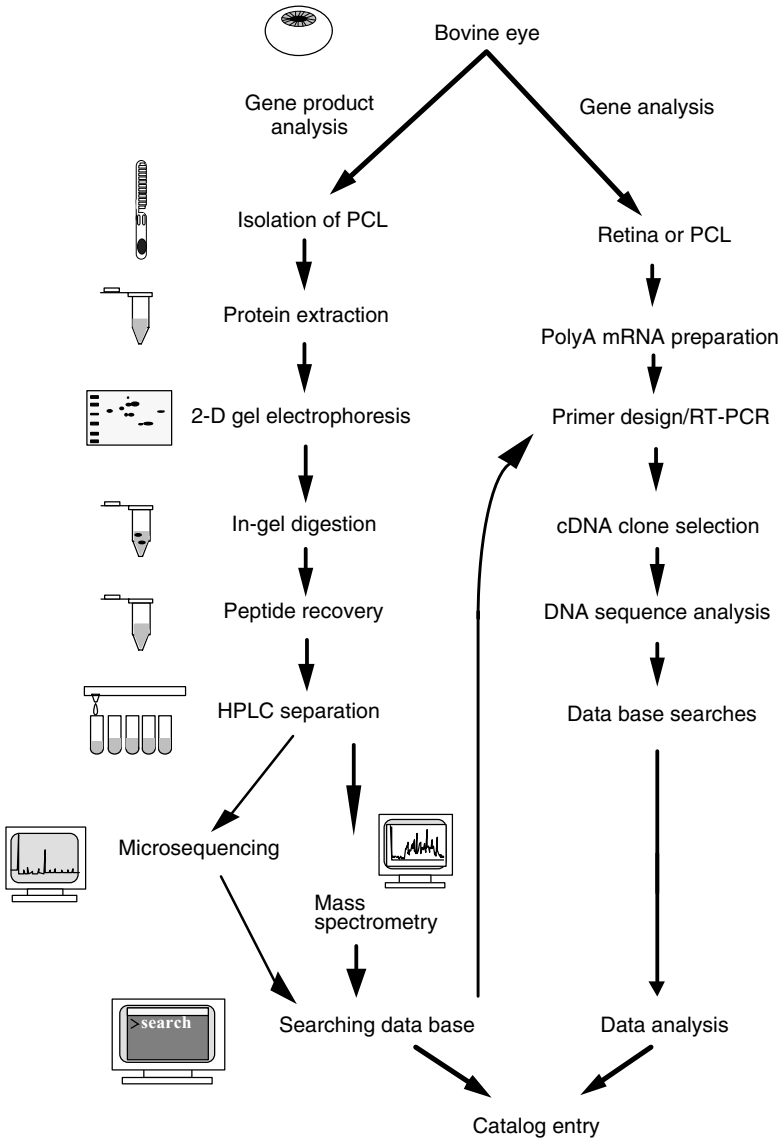

Fig. 1 A flow chart illustrating the proteomics procedures for cataloging photoreceptor proteins from the photoreceptor monolayer of bovine retina (see Fig. 9).

and ion analyzer is possible. However, the most common combinations include ESI-tandem-Q, ESI-Q-TOF, ESI-QIT, MALDI-TOF, and MALDI-QIT-TOF. FTICR is a rather expensive mass spectrometer and both ESI and MALDI ionization methods are common to FTICR. In any case, what a mass spectrometer does is to measure the mass of ionized molecules in the form of m/z.

2.3 Genome Information: a Prerequisite for Peptide Mass Fingerprinting

The ability of mass spectrometry to measure the m/z value of peptides with high sensitivity and accuracy even in a mixture constitutes the experimental basis for the identification of proteins in proteomics. The method is called *"peptide mass fingerprinting,"* which is often abbreviated as PMF. In the early 1990s, several groups reported the possibility of identifying proteins based on their peptide mass fingerprints. All proteins have their unique amino acid sequences because they are all encoded by unique genes. Highly ambitious endeavors to sequence whole genome of a certain organism were planned in late 1980s. In the beginning, the genome projects progressed rather slowly. Through the early 1990s, however, the advent of automated DNA sequencing technologies together with the advancement in microcomputers and their software gradually accelerated the progress of genome projects. It is interesting to point out that since the late 1990s, the competition between the government-funded genome project led by National Institute of Health and the genome project operated by a private-sector Celera Genomics significantly accelerated the development of the human genome project. Now complete genome information is available for many bacteria, monocellular eukaryote yeast, *Caenorhabditis elegans* (worm), *Drosophila melanogaster* (fruit fly), and other model eukaryotes. The human genome has been sequenced to its rough draft in 2001, followed by its near completion in 2003. The genome projects of rodents such as rat and mice, both of which serve as excellent model systems for biomedical research, will also be completed in the near future. In the case of *D. melanogaster*, the whole DNA sequence of its genome has been known and available through the Internet since 2000. Annotation of the DNA sequence combined with all the information assembled from studies of cloning individual genes predicts 14 431 open reading frames (ORFs). This indicates that *Drosophila* is likely to have about 14 000 different kinds of proteins expressed during its entire life cycle. Suppose one discovers a protein of interest and uncovering its identity appears to be important for the further development of the ongoing project. For the practice of PMF, it is necessary that the protein of interest is isolated from other proteins and displayed in a certain reproducible way. In the early phase of proteomics around 1995, 2-D gel electrophoresis has been the major technical tool for the display and discovery of a protein of interest. However, in recent years, the capabilities of 2-D gel electrophoresis, when applied to a total protein extract of biological samples, has been challenged. The first weakness is the limitation in the capacity of 2-D gel electrophoresis to display a large number of proteins at once. The human genome is estimated to encode more than 30 000 proteins. Currently, there is no 2-D gel electrophoresis system to display proteins in the order of tens of thousands. However, as discussed in the previous chapter, it is unlikely for one type of cell to express all the proteins. Therefore, in practice, the total number of proteins that one has to display on one 2-D gel is a fraction of 30 000. We have no reliable data regarding how many proteins are actually expressed in one type of cell under a given physiological condition. It is speculated that probably the number is 5000 $\sim$ 10 000. The maximum number of proteins that can be displayed depends on the gel system used. However,

it would be safe to say that 3000 ~ 4000 is the maximum displaying capacity of a 2-D gel at best. The second weakness, which is somehow related to the first problem, is the difficulty of displaying minor proteins on a 2-D gel when major proteins are present. It is speculated that the dynamic range of protein expression can be in the order of $10^5 \sim 10^6$. Therefore, if the protein sample contains several major proteins, then the minor protein components tend to be masked on a 2-D gel. This type of situation will be observed in the analysis of body fluids such as blood. The third weakness is the difficulty of displaying membrane-bound proteins on a 2-D gel, especially of the O'Farrell's type. As mentioned earlier, the 2-D gel system developed by Ames and Nikaido would ameliorate this difficulty. However, each membrane protein has its own characteristics; there is no guarantee for the complete solubilization and the subsequent display of membrane-bound proteins on a 2-D gel. Because of these disadvantages of 2-D gel electrophoresis, other techniques for protein display and analysis have been actively sought. One major advance in this direction, sometimes claimed as a technique "beyond 2-D gel," is the development of multidimensional high performance liquid chromatography (HPLC). In this technique, the whole protein mixture will be extracted and subjected to HPLC at least twice (two-dimensional or 2-D) or more times (multidimensional). The resins packed in the HPLC columns have "orthogonal" analytical properties so that the separation in each step will not be redundant, but rather complementary, making the separation of each protein thorough. It should be noted, however, that even a carefully designed and performed multidimensional HPLC protocol could suffer from technical imperfections such as incomplete solubilization of proteins and peptides or failure in effective elution of those molecules from the columns. The effectiveness of multidimensional HPLC for displaying the proteome must be tested empirically for each proteomics application.

2.4 Peptide Mass Fingerprinting

Suppose that, after an intensive investigation, a protein is isolated and speculated to be responsible for a certain physiological and/or pathological activity. For example, the protein of interest can be displayed as a spot on a 2-D gel or can be fractionated as a distinctive elution peak on an HPLC. It should be noted that a 2-D gel that has been run and archived many years ago can still serve as a sample source for PMF (Matsumoto and Komori, the procedure for PMF is summarized in Table 1). There are three steps in PMF:

1. *Endopeptidase digestion of the protein of interest.* In most of the PMF, trypsin, which digests the carboxyl termini of lysine (K) and arginine (R), is the endopeptidase of choice. Other endopeptidases can also be used. In Fig. 2, an example is shown when the protein of interest was isolated on a 2-D gel. In-gel digestion is preferentially used for the digestion of proteins isolated on either one-dimensional or 2-D gel electrophoresis; although other methods such as digestion after electroelution of the protein or digestion after blotting on a membrane filter can be used, the in-gel digestion is less labor-intensive and yet effective. In-gel digestion of a 2-D gel protein spot followed by mass spectrometry was reported in the mid-1990s by several groups.

Tab. 1 Peptide mass fingerprinting (PMF) consists of three steps of experimental operation; (1) in-gel digestion of protein by trypsin (1 ~ 10), 2) MALDI-TOF MS (11 ~ 12) and 3) PMF search through the Internet database (13 ~ 15).

In-gel digestion
1. Excise the protein spot out. Destain the gel piece in 50% acetonitrile (MeCN)/100 mM NH_4HCO_3, pH 8.0
2. Dry the gel piece briefly.
3. Apply 2 μL (1 μL each for two times) of TPCK-treated trypsin (Promega, Madison, WI, USA) solution (1 μg/μL in 50 mM acetic acid) to the gel piece.
4. Cover the gel piece with 50 μl of 2.5 mM NH_4HCO_3.
5. Digest at 30 °C for ca. 12 h.
6. Suck up the solution and keep it.
7. Extract the digested peptides with 60% MeCN/0.1% trifluoroacetic acid (TFA) with shaking for 1 h.
8. Mix above 6 and 7 solutions and freeze-dry the peptide mixture.
9. Dissolve the residue in 5-μL water.
10. Submit 1 μL of the obtained sample to MALDI-TOF MS.
Mass spectrometry by MALDI-TOF MS
11. Mix 1 μL of the tryptic peptides with 1 μL of matrix solution consisting of 10 mg/ml α-cyano-4-hydroxycinnamic acid (α-CHCA) in 50% MeCN/0.1% TFA in a plastic tube and apply 1 mL on a sample plate.
12. Dry the sample and measure the MALDI-TOF spectrum.
Peptide mass fingerprinting (PMF)
13. Read the mass numbers of the major peaks.
14. Search PMF through MS-Fit, and so on. If the search hits a promising candidate for protein, retrieve the full sequence.
15. Reevaluate the PMF in reference to the full sequence of the candidate.

2. *Mass spectrometry*. Mass spectrometric measurement of the tryptic digest of a target protein can be made by either of the two types of mass spectrometers: electrospray-ionization (ESI) mass spectrometer or matrix-assisted laser desorption/ionization (MALDI) mass spectrometer. The ESI ion source is often interfaced with a quadrupole, quadrupole ion trap, or time-of-flight mass analyzer. The MALDI ion source is commonly interfaced with a TOF mass analyzer. The ESI ion source has a tendency to produce multiply charged peptide ions. In contrast, the MALDI ion source produces mainly singly charged peptide ions and thus the interpretation of the mass spectrum is straightforward. For the initial stage of PMF, a MALDI-TOF mass spectrometer (MALDI-TOF MS) is often used. In Fig. 3, a PMF procedure by MALDI-TOF MS is illustrated.
3. *PMF by database search*. After measuring the peptide masses created by an endoprotease such as trypsin, the mass numbers will be searched through a database. A conceptual scheme for fingerprint matching is illustrated in Fig. 4. The search is usually performed through the Internet, although the use of stand-alone databases for the search is also possible. In this particular case shown

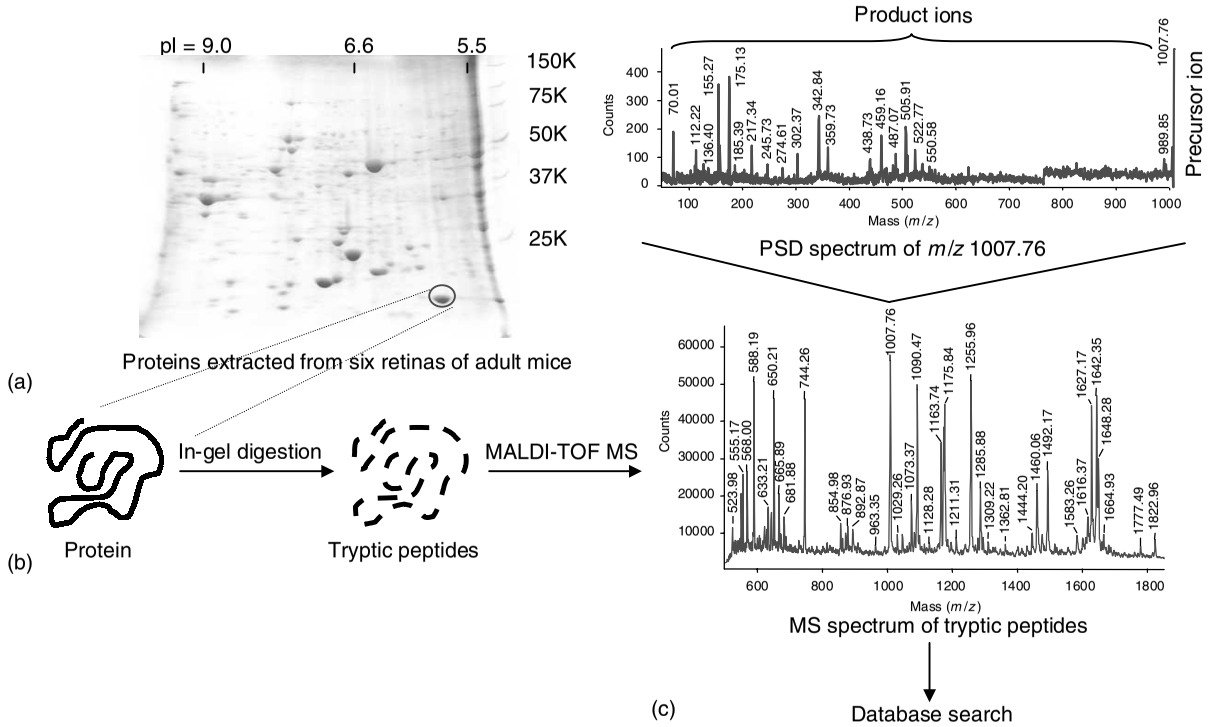

Fig. 2 (a)Outline of proteomics investigation starting from a protein displayed on a two-dimensional gel (a). The protein of interest is excised and digested by trypsin and the peptide mass fingerprint is taken by MALDI-TOF MS (b). Database search will identify the candidate protein, which will be confirmed by a PSD spectrum analysis (c).

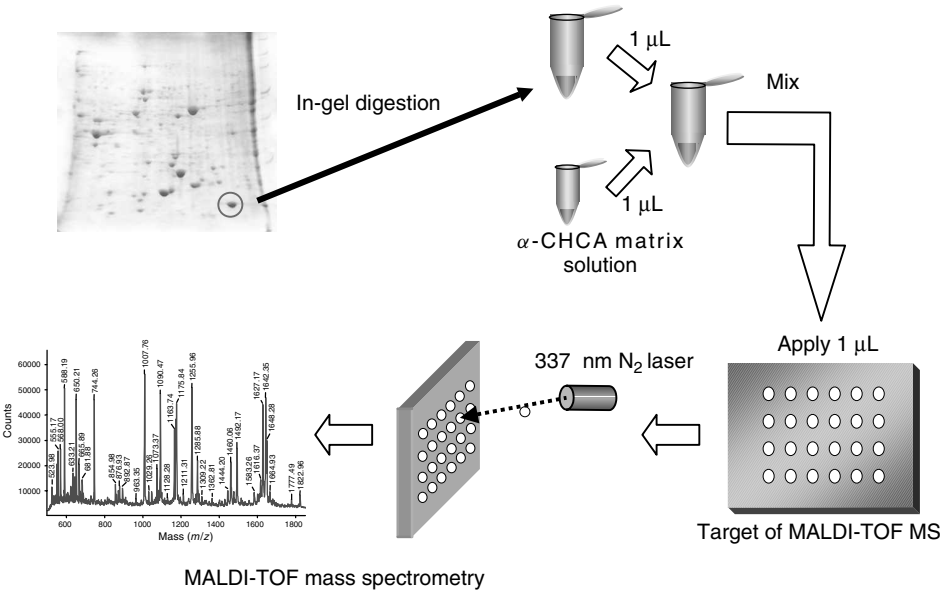

Fig. 3 Procedural outline of peptide mass fingerprinting by MALDI-TOF MS. After the in-gel digestion of the protein of interest, the mixture of tryptic digests is mixed with matrix solution containing α-cyano-4-hydroxycinnamic acid (α-CHCA) and spotted on a MALDI-TOF MS sample plate. The irradiation of the mixed crystals between the peptides and α-CHCA by 337 nm N_2 laser produces mostly singly charged ions. The m/z value of each peptide ion is measured at high accuracy and sensitivity.

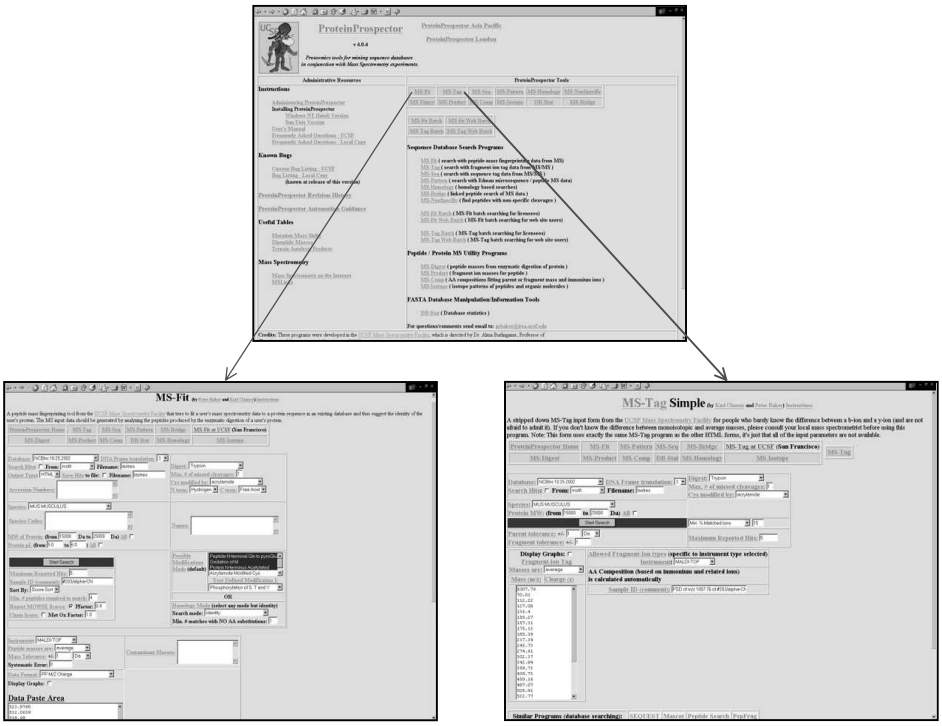

Fig. 5 An example of peptide mass fingerprinting database search: MS-Fit and MS-Tag. In MS-Fit (Lower left), the *m/z* values of the peptide ions are used for inquiries. In MS-Tag (Lower right), the *m/z* values of fragment ion tags are used for inquiries. In both cases of database search, other parameters such as ''species,'' ''the protein molecular weight range,'' and ''the tolerance of mass measurement,'' and so on can be specified. All the print outs shown in Figs. 5, 6, and 8 are the results of peptide mass fingerprinting using Protein Prospector (http://prospector.ucsf.edu/).

in Fig. 5, MS-Fit in Protein Prospector at http://www.prospector.ucsf.edu/ was used. Other database sites usable for PMF include MASCOT at http://www.matrixscience.com/, ProFound at http://prowl.rockefeller.edu/, and PeptIdent at http://www.expasy.org/. The output of MS-Fit search

Fig. 4 The concept of peptide mass fingerprinting: The amino acid sequence of the target protein is initially unknown (a). The digestion of the protein by trypsin creates a mixture of peptides. The following mass spectrometry gives the *m/z* values of tryptic peptide ions (b). If the amino acid sequence of the protein is known, all the peptides generated by the tryptic digest can be predicted by a theoretical (*in silico*) digestion. In a real experiment, however, it is unlikely that the mass spectrometric measurement will reveal all the digested fragments. In this particular case, the matched peptides covered only 72% (126 out of 173 amino acids) of the protein. ''Peptide mass fingerprinting'' is a practice to predict the identity of the target protein based on the observed masses of the peptide fragments.

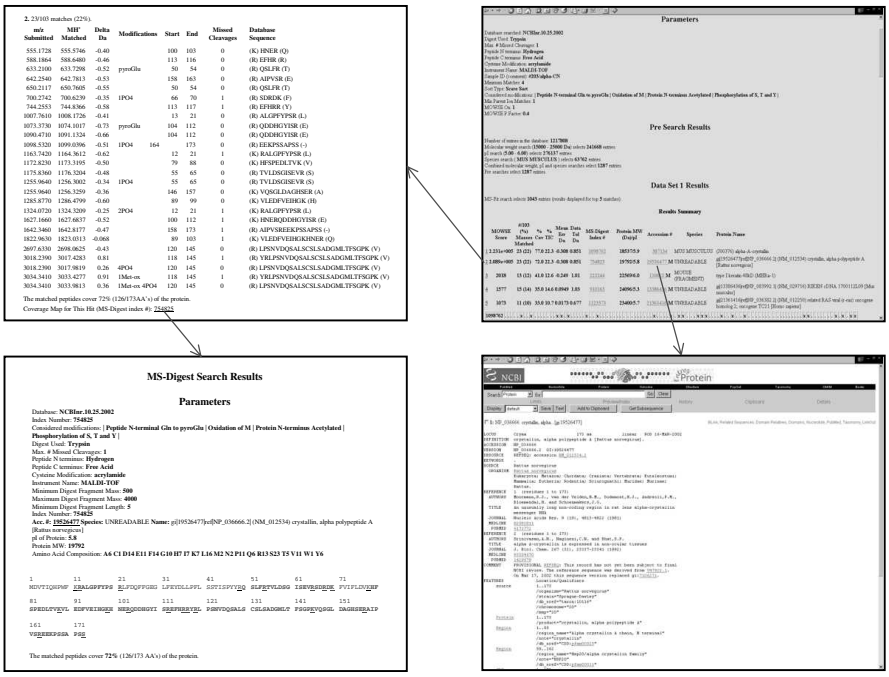

Fig. 6 The results of MS-Fit database search indicated in Fig. 5 (shown in the upper right corner). Clicking each hyperlink will output: (1) NCBI Protein Database Entry (by clicking Accession #; shown in the lower right), (2) the calculated and the observed fragments including posttranslational modifications (by clicking the candidate listing; shown in the upper left), and (3) the MS-Digest Search Result (by clicking MS-Digest Index #; shown in the lower left).

shown in Fig. 5 is shown in Fig. 6.

2.5 Confirmation of the Candidate Protein in Peptide Mass Fingerprinting

In an ideal case of PMF, all the predicted (*in silico*) fragments of the protein of interest are supposed to be confirmed in the mass spectrum. Practically, though, a total coverage of peptide mass fingerprints is unlikely to be achieved from many reasons, including incomplete digestion, low ionization efficiencies of some of the proteolytic peptides, loss of material during sample processing, and posttranslational modifications of amino acid side chains. Observation of peptides with unexpected masses, that is, ''orphan masses,'' is rather common and is attributed to (1) posttranslational or artifactual modification, imperfect proteolysis, and/or contaminated proteins in the case of successful protein identification and (2) false positive identification of a protein.

2.5.1 Confirmation by ''Orthogonal'' Type of Data

In order to increase the confidence of the PMF, further experiments need to be performed. One way is to incorporate ''orthogonal data types'' in addition to the original PMF. The orthogonal data types include (1) chemical modification such as methyl esterification (increase of

14 mass units) on aspartic acid, Glutamic acid, and C-terminus carboxyl groups, (2) iodination on tyrosine and histidine residues (increase of 126 mass units), (3) hydrogen/deuterium exchange on all amino acids (increase of one mass unit per exchanged atom), and others. One may extend the orthogonal data types into other data types; given the amino acid sequence of the candidate protein, one may predict many properties and results that can be derived by further experiments. For example, if an antibody specific to the candidate protein is available, a western immuno blot will give further evidence. Alternatively, partial Edman sequencing of the N-terminus or the N-termini of internal peptides after appropriate endopeptidase digestion and peptide isolation will also give orthogonal type data for further confirmation. Most importantly, after this initial stage of discovery, the candidate protein will emerge and a hypothesis will be made. In all the scientific investigations, further experiments must be carried out to confirm the hypothesis. If the assignment of the protein identity is incorrect, the following experiments will produce contradictory results, resulting in the correction of the old hypothesis to a new hypothesis. This cyclic process was declared by Peirce as part of abductive inference.

2.5.2 Confirmation by Peptide Fragmentation by MS/MS

Mass spectrometry can create further evidence for the confirmation of the candidate protein if the machine is equipped with collision-induced dissociation (CID) capability. For this purpose, the mass spectrometer needs to have at least two ion mass analyzers. This can be achieved in two ways: (1) by connecting two ion mass analyzers in series, for example, such as a tandem quadrupole (tandem Q) mass spectrometer or a tandem time-of-flight mass spectrometer (TOF-TOF), and (2) by connecting two different types of ion mass analyzers, for example, such as quadrupole time-of-flight (Q-TOF) mass spectrometer or quadrupole ion trap time-of-flight (QIT) mass spectrometer. These mass spectrometers enable a real CID fragmentation to confirm the candidate proteins from the daughter ions and they are at the higher end in cost.

A MALDI-TOF mass spectrometer equipped with a reflectron can also obtain a fragmentation spectrum through ''post-source decay (PSD)'' mechanism. In the PSD process, the ion to be analyzed will be selected and separated through an electric mirror called ''reflectron.'' An example is shown to confirm a peptide ''ALGP-FYPSR'' in Fig. 7. All the expected ions in the fragmentation process can be predicted by computer algorithm, as illustrated in Fig. 8.

3 Logic in Proteomics

3.1 Proteomics and Abductive Inference

The advancement of medical biosciences in the past decades has accumulated massive amounts of information due to the rapid technological development in every relevant area. The increase in knowledge and technologies in molecular biology has played an especially significant role in directing the researchers toward molecular medicine. Molecular biology in the modern context can be said to have started when the double helical structure of DNA implying the mode of its replication was revealed by Watson and Crick in 1953. Half a century later, the draft of human

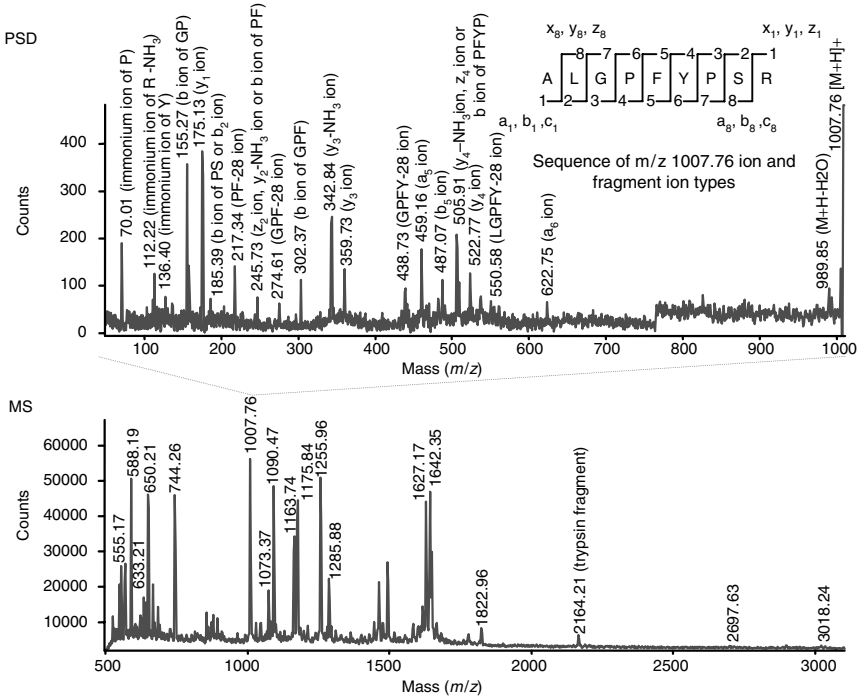

Fig. 7 An example of peptide fragmentation by PSD by MALDI-TOF MS. The ion at $m/z = 1007.76$ (shown in MS) was selected and analyzed by PSD (shown in PSD). The fragment ions shown support the assignment of the $m/z = 1007.76$ peak to be the peptide α-A-crystallin amino acid 13–21 with the sequence "ALGPFYPSR."

genome was completed in 2001. The draft of the human genome marks an epoch and summarizes all the efforts in the participating areas in biomedical sciences. During the past half century, the logical approaches that molecular biologists used are based mainly on "reductionism"; a scientific strategy and belief that a deeper understanding would be possible by investigating entities at more and more miniscule dimensions (see, for example, "Methodological reductionism" pp. 750, The Oxford Companion to Philosophy). The first and most triumphant reductionist approach in modern biochemistry took place when Eduard Büchner (1860–1917) showed that the cell-free systems of yeast are still capable of fermenting glucose in a test tube. The reductionist approach flourished since then toward the middle of the twentieth century, establishing the major metabolic pathways including glycolysis, gluconeogenesis, glycogen metabolism, citric acid cycle, pentose phosphate cycle, biosynthetic pathways of amino acids and nucleotides, catabolism of fatty acids, and others. Since the emergence of the Watson-Crick's double helix model of DNA, the trend of biochemical investigations shifted toward topics other than metabolism and a new area called molecular biology was gradually established in 1970s. The completion of the draft of human genome announced in 2001 is an epoch-making event, eloquently summarizing the past half a century of molecular

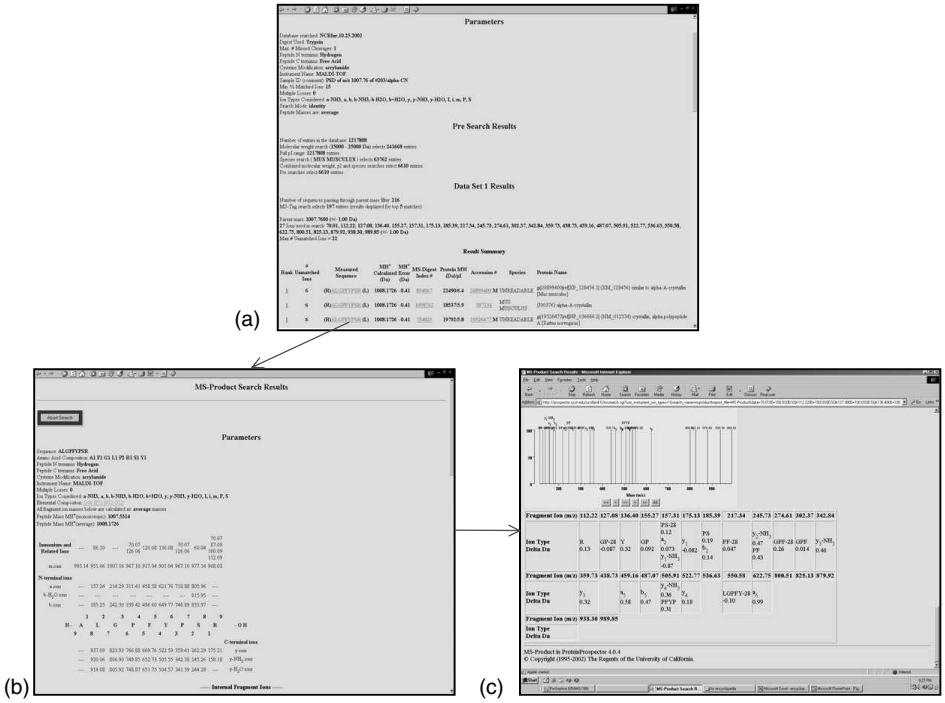

Fig. 8 The peptide fragments induced in the MS/MS process can be predicted by computer algorithm. Clicking the measured sequence (in the upper figure) outputs the MS-Product Search Results shown in (b) and (c).

biology. The initiation and substantial acceleration of progress in genome projects of bacteria, simple eukaryote models such as yeast, nematode, and fruit fly, and vertebrate models such as rodents took place in the late 1980s through the early 1990s. It is in this period that the proteomics was prepared and initiated.

The logic and strategies of proteomics investigation are novel and unique compared to those in conventional biochemistry and molecular biology. The reductionist approach in these areas has its origin in the use of cell-free systems and all subsequent efforts to fractionate the components. This approach constitutes the backbone of most of the disciplines in modern natural sciences including physics and chemistry. The arguments that have been employed in modern science are said to be classified in two categories; deduction and induction. However, it appears that the logical backbone of proteomics approach is ''abductive inference or abduction,'' which is completely different from either deduction or induction.

Umberto Eco explains the difference between deduction, induction, and abduction as follows: ''Suppose I enter a room and there find a number of bags, containing different kinds of beans. On the table there is a handful of white beans; and after some searching, I find one of the bags contains white beans only. I at once infer as a probability, or as a fair guess, that this handful was taken out of

that bag. This sort of inference is called making a hypothesis''. Eco continues as follows:

In the case of logical *deduction* there is rule from which, given a case, I deduce a result: *All the beans from this bag are white – These beans are from this bag – These beans are white.*

In the case of *induction,* given a case and a result, I infer a rule: *These beans are from this bag – These beans are white – All the beans from this bag are white* (probably).

In the case of hypothesis or *abduction,* there is the inference of a case from a rule and a result: *All the beans from this bag are white – These beans are white – These beans are from this bag* (probably).

– Umberto Eco, ''A Theory of Semiotics''

If we follow Eco's format, the logical structure of PMF can be represented by the following three statements:

1. Gene X is translated into protein Y. Protein Y, if digested, will produce a peptide mass fingerprint represented by a set of mass (y1, y2, y3, . . .).
   (This is what Eco designates a ''rule.'')
2. The digestive products of protein A gave a peptide mass fingerprint represented by a set of mass (y1, y2, y3, . . .).
   (This is what Eco designates a ''result.'')
3. Protein A is the same entity as protein Y and is encoded by gene X.
   (This is what Eco designates a ''case.'')

In Table 2, the relationship between deduction, induction, and abduction is summarized. Thus, the argument involved in PMF is an example of abduction as explained in Table 2. Note that neither rule nor result requires precise knowledge of the identity of protein encoded by gene X.

Tab. 2 Deduction, induction, and abduction.

In the case of deduction, the argument follows as indicated below: Rule: Gene X is translated into protein Y. Protein Y, if digested, will produce a peptide mass fingerprint represented by a set of mass (y1, y2, y3, . . .). Case: Protein A is the same entity as protein Y and is encoded by gene X. Result: The digestive products of protein A gave a peptide mass fingerprint represented by a set of mass (y1, y2, y3, . . .). The conclusion derived by deduction is always true.
In the case of induction, the argument follows as indicated below: Case: Protein A is the same entity as protein Y and is encoded by gene X. Result: The digestive products of protein A gave a peptide mass fingerprint represented by a set of mass (y1, y2, y3, . . .). Rule: Gene X is translated into protein Y. Protein Y, if digested, will produce a peptide mass fingerprint represented by a set of numbers (y1, y2, y3, . . .). The conclusion derived by induction could be either true or false.
In the case of abduction, the argument follows as indicated below: Rule: Gene X is translated into protein Y. Protein Y, if digested, will produce a peptide mass fingerprint represented by a set of numbers (y1, y2, y3, . . .). Result: The digestive products of protein A gave a peptide mass fingerprint represented by a set of numbers (y1, y2, y3, . . .). Case: Protein A is the same entity as protein Y and is encoded by gene **X**. The conclusion derived from abduction is actually a hypothesis that needs to be proven by further experiments.

3.2 Advantage of Proteomics Approach over Conventional Hypothesis-based Investigation

The logical structure of proteomics investigation as explained in 3.1 renders a unique advantage that does not exist in conventional hypothesis-based investigation. The distinguishing characteristic of abductive inference is the fact that it requires no initial hypothesis. This is because *abduction is a process of inferring to the best explanation. Abduction, instead of being based on a hypothesis, will create a hypothesis.* This characteristic in the logical structure of proteomics approach makes it suitable for the investigation of complex systems such as cellular signaling and gene expression. The wider the system to be investigated in biomedical sciences, the more complex and nonlinear the underlying molecular mechanisms will be. The most extreme cases include diagnosis of diseases. Abduction has been evaluated to be the right and practical logic of diagnosis. In a similar context, abductive inference in proteomics investigation will be a powerful tool to study the diagnostic and pharmacological aspects of human diseases. There is no surprise in observing the fact that many pharmaceutical/biotechnology companies have initiated and invested substantial resources along this line, resulting in new areas such as pharmaceutical proteomics or proteomics of diseases. A unifying theme in all these efforts is the holistic character of approach. Expected prospective areas using proteomics approach include the following: cancer diagnosis, disease diagnosis from body fluids, pharmacological screening, toxicology, hormone research, and diagnosis of infection. In fact, the applicability of proteomics investigation to medicine is unlimited.

4 Proteomics under a Particular Theme: Ocular Proteomics

Although proteomics techniques are high throughput in nature, it is more sensible to reduce the variables in the original samples as much as possible in order to make the interpretation of the results simpler. Practically speaking, each proteomics investigator is likely to have a specific target. ''Ocular proteomics'' is illustrated here as an example. All the visual information is initiated when photons reflected from the visible objects get absorbed by the retinal (i.e. vitamin A aldehyde) chromophore in the visual pigment molecules rhodopsin and cone visual pigments. These visual pigments constitute the photosensitive membrane structure of photoreceptor cells in the retina. The retina contains, in addition to photoreceptor cells, other types of neural and glial cells in order to maintain its function. The neural retinal cells process visual signals prior to the visual cortex of the CNS. There are numerous diseases reported in which malfunction and deterioration of retinal cells occur. Some retinal degenerative diseases are apparently caused by mutations by retinal specific genes, implying that protein malfunction causes the retinal degeneration. Therefore, cataloguing all the proteins expressed in the retina will be a useful resource for the understanding of retinal function and its malfunction at the protein level.

An effort has been made to initiate cataloguing proteins expressed in the photoreceptor cell layer of bovine retina compared to the rest of the retina from which the photoreceptor layer has been depleted. In order to dissect the retina, a tissue printing method was used, as illustrated in Fig. 9. The variation of this

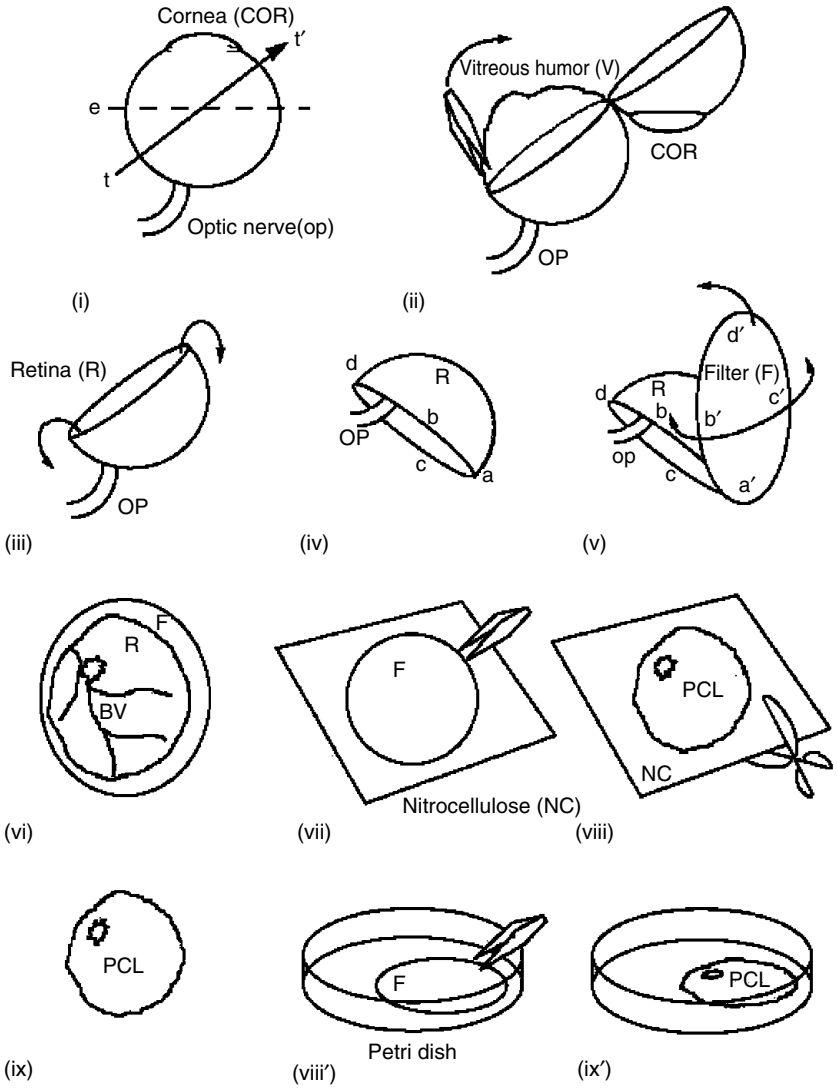

Fig. 9 A schematic diagram for preparation of the photoreceptor cell monolayer. (i) The eyeball is cut obliquely along the line t to t'. Cornea (COR), Optic nerve (OP). (ii) Vitreous humor (V) is removed from the eyecup. (iii) & (iv) The dissected eyecup is inverted. Retina (R). (v) & (vi) The retina is transferred to a Whatman filter paper (F) and lifted. (vii) The filter paper is overlaid face-side down onto a nitrocellulose membrane (NC). (viii) As the filter paper is lifted, the photoreceptor cell monolayer (PCL) remains on the nitrocellulose membrane. The excess margin of NC is removed with scissors. (ix) The PCL preparation is obtained. (viii') As a modification, a plastic Petri dish is used instead of the nitrocellulose membrane. (ix') The PCL transfers onto the Petri dish.

method can be used for other tissues if cells of significant similarity form a layer detachable from other types of cells. After tissue printing of the photoreceptor cells, the separated layers were examined by morphology (Fig. 10, left). Each layer of preparation was processed for 2-D gels (Fig. 10, right). The major 2-D gel spots on the photoreceptor layer (PCL) were excised and PMF was performed. The results of PMF are summarized in Table 3. By comparing the 2-D gels in Fig. 10 and Table 3, we conclude that four protein spots are expressed more abundantly or even exclusively in the PCL layer; Spot 1, Spot 8, Spot 9, and Spot 12. The protein represented by Spot 1 is IRBP, which is an extracellular protein assumed to be responsible for carrying retinoids between the pigment epithelial cells and the photoreceptor cells. The proteins represented by Spot 8 and Spot 9 are aspartate aminotransferase (AAT) and creatine kinase (CK) respectively, both of the mitochondrial type. Both of these enzymes are crucial components of the energy metabolism in the mitochondria. The protein represented by Spot 12 is the β subunit of transducin, which is involved in the G protein–coupled receptor signaling in the photoreceptor excitation and, therefore, is highly specific to the photoreceptor cells. The protein spots other than 1, 8, 9, and 12 also exist abundantly in the rest of the retina (Fig. 10). Those proteins expressed in high abundance in the entire retina are components of the glycolysis, as illustrated

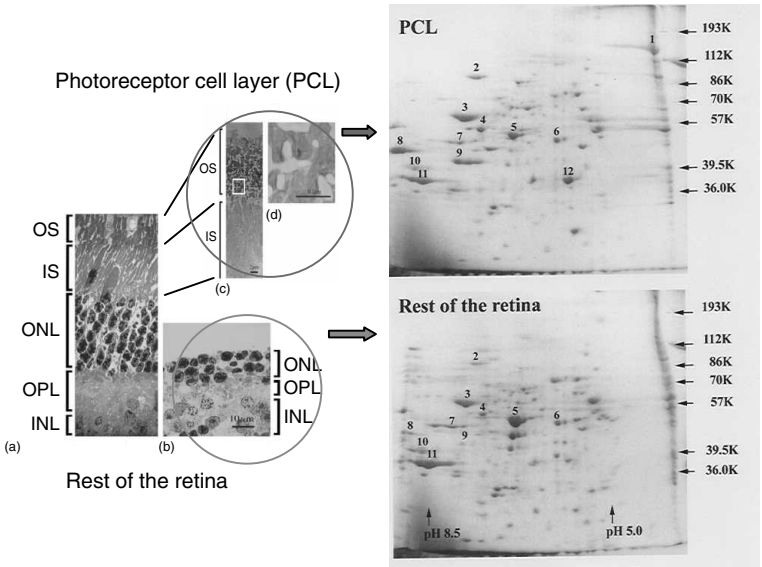

Fig. 10 Electron microscope images (Left) of the bovine retina (a), residual retina after removal of the photoreceptor cell monolayer (b), PCL adhered to nitrocellulose (c). Figure (d) illustrates the enlarged portion of OS as indicated by a square in Fig. (c). OS, outer segments; IS, inner segments; ONL, outer nuclear layer; OPL, outer plexiform layer; INL, inner nuclear layer. Each bar in the figures indicates dimension. The PCL sample and the rest of the retina were then subjected to 2-D gel electrophoresis (Upper and Lower Right).

Tab. 3 Major photoreceptor cell proteins assigned. MW, molecular weight in kilodaltons; pI, isoelectric point.

Spot #	*Assignment*	*MW/pI*	*Comments*
1	IRBP	138 kDa/5.0	Retinoid metabolism/extracellular
2	cis-Aconitase	82.7 kDa/7.6	TCA cycle/mitochondrial
3	Pyruvate kinase	55 kDa/7.7	Glycolysis/cytosolic
4	F1-ATPase	55.3 kDa/8.6	Respiratory/mitochondrial
5	Enolase	50 kDa/5.9	Glycolysis/cytosolic
6	Unknown		
7	Phosphoglycerate kinase	47 kDa/8.0	Glycolysis/cytosolic
8	(AAT)	45 kDa/9.2	Mitochondrial
9	Creatine kinase	43 kDa/7.2	Mitochondrial
10	Pyruvate dehydrogenase	41 kDa/8.6	Glycolysis/cytosolic
11	Glyceraldehyde 3-phosphate dehydrogenase	36 kDa/8.5	Glycolysis/cytosolic
12	Transducin-β	37 kDa/5.9	Phototransduction/membrane

in Fig. 11. From these results, one may conclude at least two things: (1) in bovine retina, the most abundant classes of proteins include the enzymes that are responsible for basic metabolism such as glycolysis, and (2) in the photoreceptor layer, two enzymes, that is, AAT and CK in the mitochondria responsible for the energy metabolism, are abundant compared to the rest of the retinal layer excluding the photoreceptor cells. Interesting conjectures emerge from these results. These conjectures can be evaluated by questions such as follows: (1) Do the mitochondria in the photoreceptor cells express larger quantities of AAT and CK compared to those in the rest of the retina? (2) Is the role of AAT in the photoreceptor cells to bypass the tricarboxylic acid cycle? These questions are being asked on the basis of a new set of hypotheses that did not exist before the experiments. Therefore, the whole process of proteomics approaches follows the method of *abductive inference* (or *making hypotheses*) that Peirce formulated. It should be noted that, based on these new hypotheses, another set of experiments will be performed and that the experiments should be conducted on the basis of hypotheses through conventional investigational logic, hence not by the "abductive inference" *per se* used in the very beginning of inquiries.

5 Quantitative Proteomics

The first stage of proteomics is to compare two samples, that is, a standard and the unknown sample. In order to obtain quantitative results in the comparison, there are at least two types of techniques available.

First is a rather straightforward method of obtaining quantitative data by scanning the 2-D gels by a densitometric scanner and quantifying the density of each individual spot by integration of pixels. In order to perform this type of quantitation, a scanning densitometer with an accurate calibration and software to perform the gel image analysis and pixel integration of each spot are required. Currently, there are several companies selling a scanning

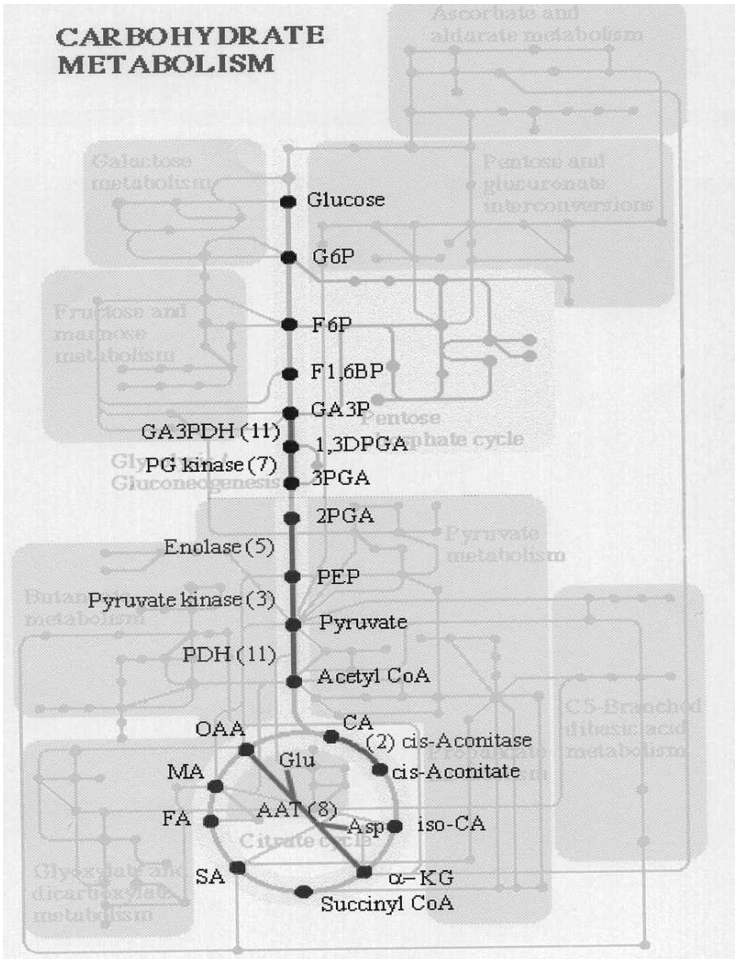

Fig. 11 The major proteins expressed in the bovine retina are enzymes in carbohydrate metabolism. The mitochondrial AAT is expressed in a larger quantity in the PCL compared to the rest of the retina. This result produces a hypothesis that the tricarboxylic cycle in the PCL operates differently from that in the rest of the retinal cells, that is, the interconversion of glutamate (Glu) and aspartate (Asp) via the bypass reaction between oxaloacetic acid (OAA) and α-ketoglutaric acid (α-KG) is more active in the PCL than the rest of the retina. The metabolic scheme is adapted from a website at Kyoto Encyclopedia of Genes and Genomes (KEGG).

densitometer and software that are suitable for this purpose.

Second group of quantitation methods utilizes modification of amino acid side chains with a couple of agents that have different physical properties such as different emission properties in a pair of fluorescent dyes or different masses caused by the incorporation of stable isotopes such as deuterium (D), which has 2 u compared to H (1 u). Carbon-13 (13 u) instead of carbon-12 (12 u) and nitrogen-15

(15 u) instead of nitrogen-14 (14 u) can also be used. In this type of quantitation, one sample (control) is labeled with a reagent with a certain property and the second sample (experiment) is labeled with a reagent with a property distinguishable from the control. Endopeptidase digestion needs to be done after or before the modification of amino acid side chains, depending on which system will be used.

For example, in a protocol called ''2-D Fluorescence Differential Gel Electrophoresis (DIGE)'', two protein samples will be modified by two different fluorescent dyes that emit at distinguishable wavelengths, and mixed. The mixture of fluorescent dye-labeled proteins will be separated on a 2-D gel. Since the pair of fluorescent dyes are designed so that the changes in the isoelectric point (pI) and the molecular weight are the same between the control and the experiment, each protein of the same kind, though originating from different samples, migrates and focuses at the same spot on a 2-D gel. With the use of a two-color scanning fluorescence densitometer, the amount of the modified proteins can be quantified.

Another example of quantitation in the second group is a mass spectrometric method in which a pair of light or heavy peptide modifier is used. ''Isotope Coded Affinity Tag (ICAT)'' is an especially successful technique that belongs to this category. In the ICAT technique, two different samples will be labeled by a derivative of a cysteine-modifier iodoacetoamide that carries an affinity tagged biotin and 8 atoms of deuterium (d_8-ICAT). A control ICAT reagent was synthesized without the 8 atoms of deuterium, making the reagent 8 u lighter than the d_8-ICAT. The two samples modified with d_8-ICAT and ICAT will be digested. The advantage of ICAT is that the affinity tag biotin can be used to purify the modified peptide fragment. After affinity purification by an avidin column, the eluate will be analyzed by an HPLC-interfaced ESI mass spectrometer. A deuterium-labeled *N*-alkylmaleimides also can be used in this type of analysis without the sophistication of affinity tag. Another method to quantify protein involves the digestion of one protein sample in the presence of ^{18}O-labeled water. The other sample to be compared will be digested in regular water (^{16}O). The former digests will make each peptide 4 u heavier than the latter. After mixing the digests and a high-resolution mass spectrometric analysis, the ratio between the two peaks separated by 4 u indicates the ratio of the protein existing in the two samples.

6 Proteomics and Molecular Medicine

The unique characteristic of proteomics approach that does not require presuppositions or hypotheses makes it an excellent tool for molecular medicine. Instead of starting from one particular protein that is supposed to be important for the understanding of molecular mechanisms underlying a disease, a proteomics approach can start from evaluating the protein expression and modification and their abnormal variance without knowing what they are in the beginning. Development of technologies in many areas in the past decades enabled us to apply a proteomics approach to virtually any area of medical biosciences. Each area of proteomics inquiry will be defined well by the set of parameters in its particular project. One can choose any input parameters that affect the system to be investigated, and, depending on the variable parameters, proteomics can be classified as, for example, ''pharmaceutical

proteomics,'' ''physiological proteomics,'' ''pathological proteomics,'' and so on. For example, with a proteomics approach, it is now feasible to initiate a project to evaluate the effect of drugs on the protein expression and posttranslational modification in a particular type of cells under a particular set of physiological parameters (pharmaceutical proteomics). Another example is that a comparison of proteins from cancerous tissues and those from normal tissues may give us a hint to initiate a new project based on a new hypothesis (cancer proteomics). Thus, the applicability and versatility of proteomics approach to the study of diseases appear to be unlimited.

Keywords

Matrix-assisted Laser Desorption and Ionization (MALDI)
Biomolecules that are cocrystallized with a much larger amount of organic compounds on a substrate are laser-ablated to accomplish desorption and ionization for mass spectrometry detection.

Time-of-Flight Mass Spectrometer (TOF)
A mass spectrometer that is used to determine the mass-to-charge ratio of gas-phase ions by measuring the flight time in a drift tube for ions.

Gel Electrophoresis
Migration of charged molecules in an electric field with gel as a medium, which is obtained for separation and/or purification of biomolecules.

DNA Hybridization
Two single-stranded DNAs with complementary sequences combine to produce a double-stranded, with hydrogen bonding between two single-stranded DNAs. Hybridization is often used for DNA sequence identification. Microarray hybridization is often used for high throughput–DNA analysis.

DNA Sequencing
A process that determines the sequence of bases in a DNA segment.

Abbreviations

ASPCR:	Allele-specific polymerase chain reaction
CF:	Cystic fibrosis
CFTR:	Cystic fibrosis transmembrane conductance regulator
ds-DNA:	Double-stranded deoxyribonucleic acid
DNA:	Deoxyribonucleic acid
DRPLA:	Dentatorubral-pallidoluysian atrophy
EDTA:	Ethylene diamine tetraacetic acid
IR-MALDI:	MALDI with an infrared laser beam for desorption
MALDI:	Matrix-assisted laser desorption/ionization

MS:	Mass spectrometry
PCR:	Polymerase chain reaction
RFLP:	Restriction fragmented length polymorphism
ss-DNA:	Single-stranded deoxyribonucleic acid
SNP:	Single nucleotide polymorphism
STR:	Short tandem repeat
TOF:	Time-of-flight
TOFMS:	Time-of-flight mass spectrometry
UV-MALDI:	MALDI with an ultraviolet laser beam for desorption
VNTR:	Variable number of tandem repeats

Recently, high-speed DNA fragment sizing has been in critical need due to its important application on genomic function, DNA sequencing, disease diagnosis, DNA typing for forensic use, and microbial analysis for bioagent identification. Mass spectrometry has played a key role in rapid DNA sizing. This article discusses the fundamental principles of mass spectrometry for DNA analysis and the advantages and disadvantages of mass spectrometry compared to other approaches. It also gives a brief historical review of the development of mass spectrometry for DNA analysis. Applications in DNA sequencing, genetic disease diagnosis, and DNA finger printing are also presented.

1 Introduction

Since the discovery of the double-helix structure of DNA by Watson and Crick, research on DNA has been a key component of biological and medical research. The major functions of DNA comprise the transmission of information through a genetic code and self-replication. Many important advances have been made in understanding the complex organization of genetic material in cells and applying genetic engineering to manipulate the replication capability. However, because of the extreme complexity of the human genome, a worldwide Human Genome Project on mapping and sequencing the entire human genome was initiated in 1988 and has been more or less completed recently. The interest in DNA sequencing has expanded to include microbial genome, mouse genome, rice genome, and others. It is also expected that the need to sequence and resequence known genes will be increased by many orders of magnitude in the coming decades. Nevertheless, nearly all the data relating to sequencing of DNA have been obtained by gel electrophoresis, which is still relatively slow and somewhat expensive. It is clear that faster and cheaper methods are in critical need. For most resequencing work, the sequencing speed and cost can be more critical than the size of DNA that can be sequenced. Mass spectrometry for DNA sizing and analysis can serve this purpose because of its short analysis time.

1.1 Time-of-flight Mass Spectrometry

The conventional method used for DNA measurement is gel electrophoresis. In this process, an electric field is applied to the gel medium to cause the drift of DNA fragments, which typically exist as charged particles. The drift velocity tends to be lower as DNA fragments become larger. However, this process is slow and needs hours to separate different sizes of DNA fragments. The DNA-sizing speed by capillary gel electrophoresis is significantly faster than slab-gel electrophoresis. Nevertheless, mass spectrometry DNA sizing is much faster than either of the methods of electrophoresis. Mass spectrometry has been used for several decades to measure the molecular weight of gas samples by mass-to-charge ratio. In order to use a mass spectrometer for molecular weight determination, the relevant molecules need to be produced in gas phase. The pressure inside the mass spectrometer needs to be less than 10^{-4} Torr in order to prevent collisions between the ions and other gaseous molecules. Owing to the practically zero-vapor pressure of DNA at room temperature, a method of producing DNA gas-phase molecules is required. Desorption of DNAs by a laser beam oran ion beam is often needed. Another approach is to introduce solvated DNA samples through electrospray or ionspray processes. Since mass spectrometry is based on the detection of gas-phase ions, a means to produce such ions is obviously needed. Ions can be produced by several different processes. These processes include charged particle ionization, photoionization, chemi-ionization, and electron-impact ionization. All these processes involve the removal of an electron from a molecule to form a positive ion. However, positive or negative ions can also be produced by attaching or detaching a charged particle such as a proton. This process is quite often achieved by a chemical process. Once the ions have been produced, various sizes of ions may be separated by electric or magnetic fields. The mass-resolved ions are then accelerated to impinge on a solid surface of low work function to generate secondary electrons, which are subsequently detected by an electron multiplier, or a channeltron or microchannel plates (MCP). Since these electron detection devices can have an amplification factor of 10^8, even a single secondary electron can be detected.

Owing to the similarity of principles between a time-of-flight mass spectrometer (TOFMS) and a gel-electrophoresis device, a time-of-flight mass spectrometer is most often used for DNA detection. A TOFMS is a device in which ions of different masses are given the same energy and are allowed to travel in a field-free space. Because of their different velocities, the ions of differing masses arrive at the end of the field-free space at different times, where an ion detector produces a time-varying electrical signal proportional to the number of ions impacting it. The amplified current signal is typically displayed on a fast digital oscilloscope, where the molecular weights can be determined by measuring the time interval between the creation of ions and the detection of ions. The ions need to be produced in a very short time interval and in a very small volume in order to achieve high resolution mass spectra. Thus, ionization by a short-pulsed laser beam is an ideal choice for a TOFMS. A schematic of a typical TOFMS is shown in Fig. 1. Ions are produced by a short-pulsed laser beam, which is typically focused to a small area in the ionization region. Ions

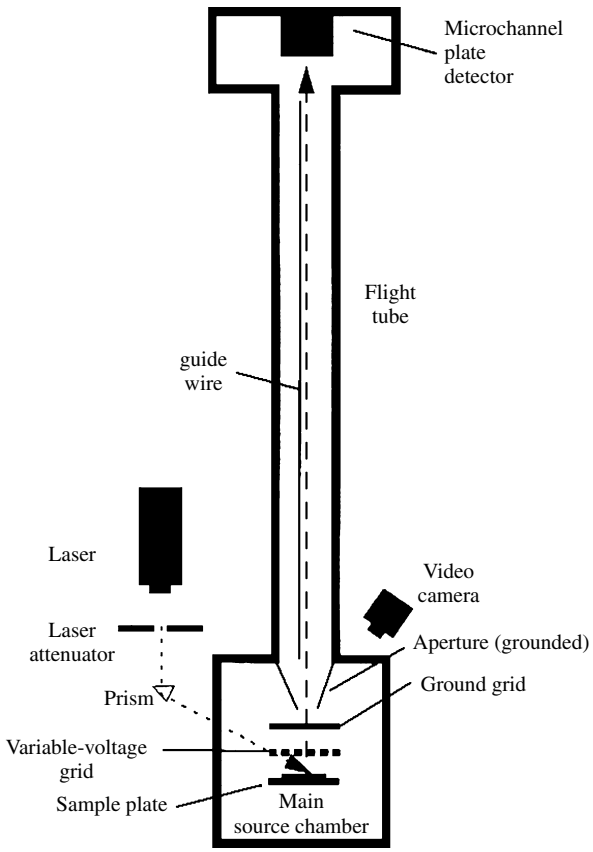

Fig. 1 Schematic of a typical MALDI Time-of-flight mass spectrometer. A laser beam is focused onto a sample for desorption and ionization through protonation/deprotonation process. UV, IR, and visible lasers have all been used for MALDI. However, most works have been done with UV-laser desorption. A video camera is typically used to observe the sample location so that the laser beam can be focused on the desired location. Pulsed-ion extraction is often used to enhance mass resolution. A guide wire is used to achieve the oscillation of desorbed ions to reduce the desorbed biomolecular ions hitting the wall of vacuum chamber. A charged particle detector such as microchannel plate is used for ion detection. Most commercial instruments have sample holder with array configuration so that multiple samples can be placed in the mass spectrometer for analysis.

are then accelerated to a uniform energy by an electric field before they go into the free drift zone. An electron multiplier or a microchannel plate is placed at the end of the drift tube to detect the ions. Since ions have different initial velocities when they are produced, the higher the acceleration energy, the lesser the effect the initial

velocity spread will have on the flight time, and the higher the mass resolution will be. On the other hand, a higher voltage gradient in the area of the ionizing laser will result in ions produced in different parts of the laser beam being accelerated through different potentials, reducing the resolution of the flight times. Better resolution is achieved with a smaller ratio of ionization radius to acceleration length. There are several ways to improve the resolution of a TOFMS. A popular approach is the reflectron TOFMS. An electrostatic lens to bend ion trajectory is typically placed at the end of the drift tube to *reflect* the ions toward the detector. This design can be used to compensate for either the initial velocity spread or the spatial spread of the ions. However, it is difficult to compensate for both velocity spread and spatial spread. Resolution ($M/\Delta M$) of 10^5 for a reflectron TOFMS has been achieved by a few groups of researchers. One major advantage of a TOFMS over other types of mass spectrometers is its speed in measuring all the masses in a sample in a very short period of time, and another is its capability of measuring ions with very high molecular weights. In principle, there are no limitations on the size of molecules that can be measured by a TOFMS if the ions can be accelerated to a high enough velocity that secondary electrons can be ejected due to the ion's impact on the ion detector. This property is critically important for the detection of DNA fragments since most DNA fragments have very high molecular weights.

A mass spectrometer can be used for molecular weight determination only under the condition that the molecular ions are produced in space. Thus, a mass spectrometer, usually, can only be used for materials with vapor pressure higher than 10^{-14} Torr at room temperature. Although the minimum vapor pressure required is very low, the vapor pressures of many materials at room temperature are even lower (lower than 10^{-14} Torr). DNA fragments are in this category. In order to use mass spectroscopy for DNA measurement, it is necessary to develop a method that places DNA fragments in space without breaking them up. Recent developments in laser desorption have been significantly successful in achieving this. A frozen double-stranded DNA fragment on a copper plate was successfully desorbed by a dye-laser beam. Gel electrophoresis was used to prove the success of laser desorption of a large amount of DNA. However, the use of mass spectrometry for DNA analysis requires both desorption and ionization.

1.2 Matrix-assisted Laser Desorption/Ionization (MALDI) for DNA Analysis

Since a mass spectrometer can only be used to detect ions, some process of ionization is necessary if only neutral DNA segments are produced in the desorption process. Ionization can be achieved either by electron detachment to form a neat positive ion or by electron attachment to form a neat negative ion. Ions can also be produced by protonation to form $(M + H)^+$ or deprotonation to produce $(M - H)^-$. Since the size of a DNA segment is usually large and some of the DNA bonding (such as the glycosidic bond) is fragile, successful soft ionization to produce parent ions without breakup is a challenge. In addition to the *soft* desorption and *soft* ionization, the third major problem is the difficulty in detecting very heavy ions. In order to use an electron multiplier or an MCP in the detection of an

ion efficiently, the ion velocity needs to be greater than 1.5×10^6 cm/s. For example, a 1000-bp DNA segment has a molecular weight of ~600 000 daltons. These ions need to be accelerated to 700 KeV in order to reach a velocity of 1.5×10^6 cm/s. Most mass spectrometer designs are not suitable for accelerating very heavy ions to the velocity required for detection. Recently, the secondary electron emission efficiency at various velocities for a few bio-organic molecules was measured and the conclusion reached was that the threshold velocity could be somewhat lower than 1.5×10^6 cm/s for larger molecules. The successful detection was attributed, at least partially, to the ejection of smaller ions when large ions hit the metal plates. Nevertheless, the low detection efficiency for very large molecular ions is a concern when using mass spectrometry for the detection of very large DNA segments.

It is clear that the use of mass spectrometers for DNA detection will require the solution of several challenging problems. However, there is a major advantage in using mass spectrometry because of the potential to achieve ultrafast speed. Using gel electrophoresis for DNA separation typically takes a few hours. If radioactive tagging is used, it can be done overnight. However, a mass spectrum can be obtained within one second. For example, a TOFMS usually needs less than one millisecond to separate different sizes of DNA fragments; thus speed is improved by many orders of magnitude. In addition, hundreds of samples can be placed in a mass spectrometer for fast analysis if an array sample holder is designed to hold multiple targets. For gel electrophoresis, tagging of radioactive materials or organic chromophore to DNA fragments is required for detection. Thus, radioactive or chemical wastes are produced. Mass spectrometry analysis eliminates the need for tagging; therefore, no waste will be produced. Although a mass spectrometer can be more expensive than a gel electrophoresis setup, the much faster speed of analysis by a mass spectrometer can drive the cost much lower on a per sample basis. For example, 1000 samples of DNA fragments can possibly be analyzed by a TOFMS within an hour. This can be particularly important for medical applications, since it may be necessary for large hospitals to analyze thousands of samples each day.

For the analysis of materials with no vapor pressure at room temperature, several desorption methods have been used to carry the analyte into space for mass analysis. Major approaches include desorption by fast-atom bombardment (FAB), secondary-ion bombardment, and laser desorption. However, none of these have been very successful for analysis of large biomolecules. Since most biomolecules are fragile, when subjected to heat or bombardment, a fragmentation process almost always occurs. However, in 1987, Hillenkamp and his coworkers discovered that large protein molecular ions can be produced without much fragmentation by laser desorption if these biomolecules are mixed with smaller organic compounds that serve as a matrix for strong absorption of a laser beam. This process is now called *matrix-assisted laser desorption* (MALD). The typical preparation technique for MALD is to dissolve biomolecular samples in solution, then prepare another solution that contains small organic compounds such as 3-hydroxypicolinic acid (3-HPA). These two solutions are subsequently mixed, and a small amount of the resulting solution is placed on a metal plate to dry. After the crystallization of the sample, the sample plate is placed in

the mass spectrometer for analysis. The molar ratio of matrix-to-analyte is typically more than 100 to 1. During a MALD process, matrix materials strongly absorb the laser energy and become vaporized, and large biomolecules are carried outward during the fast-vaporization process. Large biomolecules can be delivered into space without breakup, probably due to minimal direct absorption of laser energy; thus, *soft* desorption can be achieved. However, it has been found that biomolecule parent ions are also produced during the MALD process in addition to the expected neutral molecules. Thus, these desorbed ions can be directly detected by a mass spectrometer. This process involving matrix-assisted laser desorption and ionization at the same time is referred to in an abbreviated form as MALDI (matrix-assisted laser desorption and ionization).The mechanism of ion production has been speculated by many researchers to involve proton transfer.

Up to now, one major disadvantage of MALDI for DNA analysis has been its relatively poor mass resolution especially for large DNA fragments. In order to study the cause of poor mass resolution, velocity distributions of desorbed oligomers were studied, and it was found that the distribution more or less follows the distribution of the matrix. In general, the mass resolution of MALDI spectrum of DNA is relatively poor compared to that of small organic compounds. This relatively poor resolution is due to (1) high initial velocity distribution, (2) the inhomogeneity of DNA samples on metal plates, (3) the adducts of matrix materials or metal ions to DNAs, and (4) fragmentation of DNA molecules due to the laser ablation process. Since the velocity distribution of the DNAs are passively carried out by matrix materials, the velocity spreads are expected to be similar to the velocity distribution of the matrix material. If the molecular weight of a DNA fragment is 200 000 daltons and the molecular weight of the matrix is 100, the desorbed energy of DNA molecules can reach 50 eV, even assuming that the average kinetic energy of desorbed matrix material is near thermal. Thus, the broad distribution of ion energies of desorbed biomolecules is one important factor that limits the resolution. When a biomolecule sample mixed with matrix materials begins to dry on the plate, the process of crystal growth makes the sample distribution inhomogeneous. The thickness of the sample can also cause lower resolution. However, a reflectron TOFMS can compensate for the ionization volume to achieve a resolution higher than 1000. Since most spectra by MALDI have resolutions of only a few hundred, the limited resolution is primarily a result of adduct and fragment formation. If a biomolecule can be attached to a matrix molecule, or part of a matrix molecule, the resolution then depends on the molecular weight of the attached particle. It is also not unusual to observe alkali metal ions attached to DNA molecules. The adduct formation is strongly dependent on the matrix used. Detection sensitivity for small DNA segments (<10mer) by MALDI can reach 1 femtomole. The bigger the size of the DNA segment, the lower is the detection sensitivity.

The chemical characteristic of matrix material used in MALDI for DNA segment analysis is probably the single most critical parameter. Only a few compounds have been found to be useful matrices for oligomers. A good matrix material needs to have good solubility in the solvents used for the analyte, strong absorption at the laser wavelength, and no chemical reactivity with the analytes. In general, the matrix needs to dissolve in the solvent

in concentrations higher than 0.01 M solution. Otherwise, a high molar matrix-to-analyte ratio is difficult to achieve. The absorption coefficient at the laser wavelength needs to be higher than 3000 L $mole^{-1}cm^{-1}$; otherwise, the laser energy deposition cannot be concentrated in the top few hundred molecular layers to produce efficient desorption. It is clear that the matrix materials used cannot chemically react with the analytes. For example, strong acids tend to remove purine bases. Thus, they would not be good matrices. The glycosidic bonding of DNA is fragile and easily subject to chemical interaction. This can be a factor that makes MALDI for DNA analysis much more difficult than for protein analysis. Although a few criteria can be set up to rule out certain chemicals as good candidates for MALDI of DNA segments, the search for good matrices is still more or less trial and error.

In addition to the chemical properties of a matrix material, the amount of energy deposited by the laser is also critical for achieving good spectra. It has been shown that the relationship between biomolecule ion production and the intensity of the laser pulse is highly nonlinear. Below a threshold, no biomolecule ion signal is produced. Above a threshold, the ion production increases rapidly to a plateau. The threshold for ion production of DNA segments was found to be a few megawatts per square centimeter. However, ion signals tend to disappear when the laser intensity is so high that intense plasma is produced.

Detailed mechanisms for ion production of biomolecules by MALDI are still not well understood. However, a simple model of photoionization and photochemistry processes has been proposed to explain the production of biomolecular ions. The model suggests that a multiphoton absorption process leads to the ionization of matrix molecules, which have subsequent chemical reactions with biomolecule analytes to form ions.

The existence of metastable states of negative oligomer ions during the MALDI process has been experimentally proved. The lifetimes of small negative oligomer ions were measured to be a few hundred microseconds. The lifetimes become shorter for larger negative oligomer ions compared to that of smaller ones. These results indicate that the detection of large negative oligomer ions will be very difficult for Fourier transform, ion-cyclotron, reflectron TOF and ion-trap mass spectrometers with MALDI because of the long ion lifetimes inherently required by these instruments.

Although MALDI has been applied to detect large biomolecules with a good determination of molecular weights, it has been difficult to achieve quantitative measurements of biomolecules. The primary reasons for poor reproducibility are related to the inhomogeneous distribution of samples on substrates and the high sensitivity to changes in laser fluence. A small change in laser fluence can cause a very large fluctuation in analyte signals. When samples are prepared in a MALDI experiment, the crystallization process can make the distribution of matrix materials inhomogeneous. For example, nonhomogeneous needle-shaped crystals were observed when using 2.5-dihydroxybenzoic acid as a matrix. The signal level of analytes can be a strong function of the exact spot at which the laser desorbs. It is also known that an impurity in a MALDI process can reduce the signal levels of analytes significantly. In addition, the surface condition of the substrate can make a significant change in the threshold for the

production of plasma. In brief, it is difficult to obtain reliable measurements of absolute quantities of analytes by MALDI. If MALDI is to become a routine analytical tool, it is obvious that its capability to make quantitative measurements of analytes must be improved. When the quantity of the matrix is fixed, signals from oligomers are not linearly proportional to the quantity of the analyte. This very nonlinear relation between ion signal and analyte is mostly due to the number of layers of analyte absorbing laser energy and the detailed interaction between DNA and matrix molecules during the crystallization process. Too much of the analyte on the samples may not produce bigger signals. However, if a known biomolecule with similar chemical properties is used for an internal calibration, the signal level can become more or less independent of the laser fluence and the inhomogeneous distribution of matrix materials.

2
DNA Sizing and Sequencing by Mass Spectrometry

2.1
DNA Sizing by MALDI

Since the discovery of MALDI, many research groups have succeeded in measuring various proteins and large organic compounds by MALDI. MALDI has also been applied to DNA segments. Initially, success was limited to the detection of small DNA fragments. Then, 3-hydroxypicolinic acid (3-HPA) was found to be a good matrix for oligonucleotide detection. Both positive and negative ions were observed using 3-HPA as matrix (Fig. 2). Restriction fragment length polymorphism (RFLP) and polymerase chain reactions (PCR) are two of the most important DNA analysis methodologies discovered in the past few decades. PCR is broadly used in

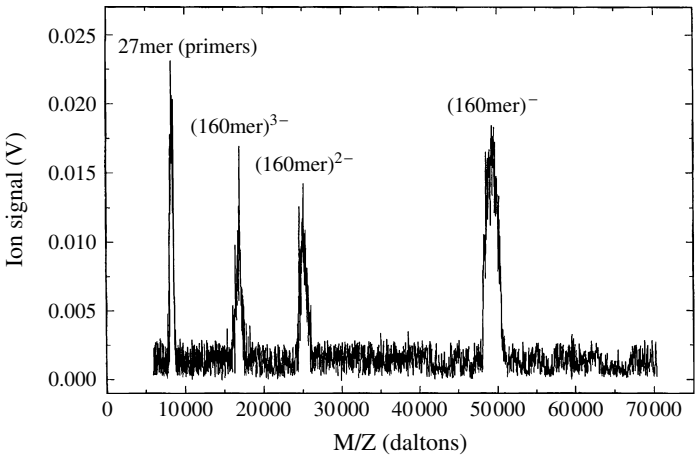

Fig. 2 Negative-ion mass spectrum of a 160-bp DNA amplified from pLB 129. The desorption laser was a fourth harmonic of a Nd-Yag laser with wavelength at 266 nm. In addition to single charged ions, doubly and triply – charged ion peaks were also observed. Although double-stranded DNA was used, only the peaks corresponding to single-stranded DNA ions were observed. It indicates that ds-DNA was probably dissociated into ss-DNA due to the interaction with acidic matrix molecule.

nearly every DNA laboratory to replicate a required segment of DNA from genomic DNAs. MALDI mass spectrometry has also been applied for RFLP and PCR products analysis. The success in using mass spectrometry for measurements of RFLP and PCR products paved the way for several important applications including disease diagnosis and DNA typing for forensic applications. With the development of an instrument to give high ion energy and the use of mixtures of matrices, MALDI was successfully used to detect double-stranded DNA (ds-DNA) of 500 bp, which was produced by a PCR amplification process (Fig. 3). However, only a single-stranded DNA was observed. This marked the first success of using MALDI for a large DNA fragment. Recently, the detection of DNA with the size of 3199 bp was reported (Fig. 4). It can be concluded that large DNA fragments can be measured by MALDI. However, the mass resolution for large DNA fragments (>300 nucleotides) is still very poor ($M/\Delta M < 50$). RFLP measurement by MALDI for S16 rDNA for a microbe has also been successfully demonstrated. (Fig. 5). It indicates that mass spectrometry is emerging as a valuable tool for DNA sizing for various applications.

2.2 DNA Sequencing

DNA sequencing is a method that not only determines the size of a DNA fragment, but also its structure. DNA contains four primary bases – adenine (A), guanine (G), cytosine (C), and thymine (T). Their chemical structures and molecular weights are shown in Fig. 6. Since there is a mechanism for translating the nucleotide sequence in DNA into the amino acid sequence of protein, DNA sequencing is critically important for biological and medical research. Current methods of DNA sequencing such as those of Sanger and Maxam-Gilbert have proven to be very useful for sequencing small DNA segments. These methods of sequencing usually

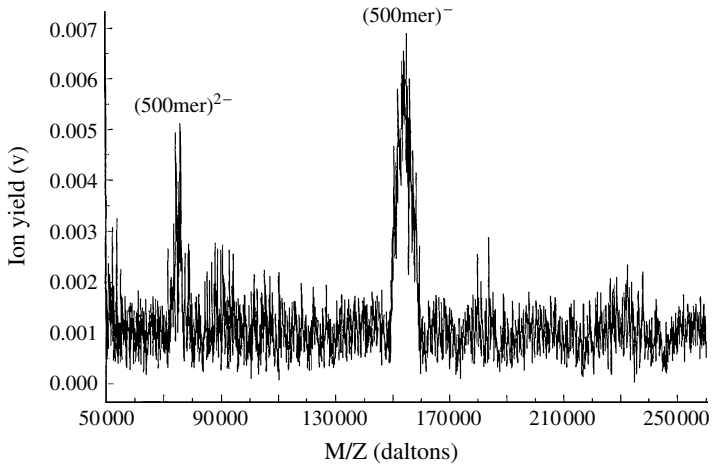

Fig. 3 Mass spectrum of a 500-bp DNA amplified by PCR from bacteriophage lamda genome. The laser fluence used was 200 mJ cm^{-2}. No peaks corresponding to ds-DNA were observed.

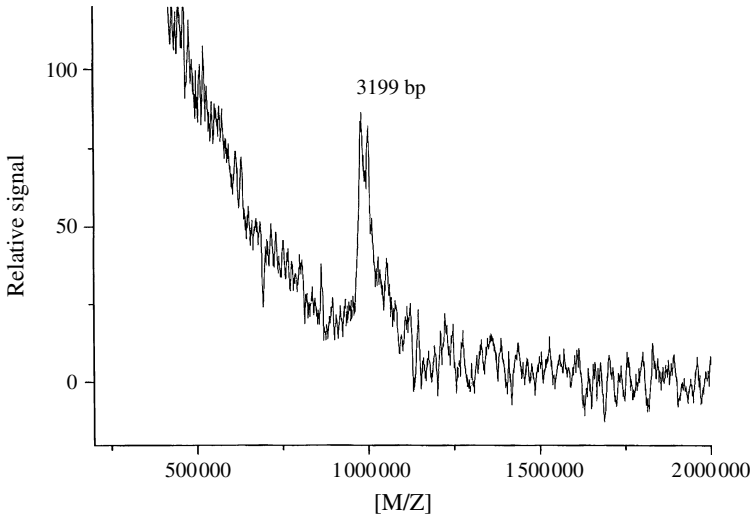

Fig. 4 Mass spectrum of a large DNA fragment of 3199 bp. It clearly indicates that large DNA segments can be detected by MALDI. However, the detection efficiency is very low due to the low yield of secondary electrons when the ion velocity is very low ($< 1 \times 10^5$ cm s^{-1}).

involve labeling fragments of DNA for identification following gel electrophoresis. Either radioactive labels such as ^{32}P or ^{35}S, or chemical labels such as fluorescent dyes are currently used. At the present time, routine DNA sequencing in most laboratories relies on the use of radioactive isotopes. The fragments are generated either chemically or enzymatically to represent all possible positions of each of the four nucleotides (A, G, C, and T). Following electrophoresis, the radioactive labels are located by autoradiography. This method is very time-consuming. With radioactive labeling, four lanes of gel are usually required to separate the fragments from a given DNA segment that terminates in A, G, C, or T. Substitution of fluorescent labels for radioactive isotopes allows the DNA fragments to be detected continuously during electrophoresis. This method usually employs four different fluorescent labels. Using these four labels, all four types of DNA fragments (A, G, C, and T) can be run in one electrophoresis lane. The uncertainty in comparing the label positions in four adjacent lanes of the gel is eliminated. Automatic sequencing instruments based on fluorescence measurements are currently commercially available. Recently, capillary gel electrophoresis coupled with the fluorescence method has also been successfully used for improving sequencing speed. However, both radioactive methods and fluorescent dye labeling methods for DNA sequencing require the use of the time-consuming gel electrophoresis. Thus, it is natural to consider using TOFMS for DNA sequencing to reduce

the sequencing time. Instead of taking several hours by gel electrophoresis, the TOFMS takes less than one millisecond to finish the separation of different sizes of DNA segments. However, the parent DNA ions must be produced with high efficiency and without serious fragmentation. Since the MALDI process has been successfully used in producing parent ions of small DNA segments without serious fragmentation, it can have an important role in the future of fast DNA sequencing especially for re-sequencing.

2.2.1 DNA Sequencing by Mass Spectrometry with DNA Ladders

DNA sequencing has been broadly used for biomedical research and clinical applications during the past two decades. Rapid and reliable DNA sequencing can also be very valuable in forensic applications. In the conventional sequencing approach, different sizes of DNA ladders, which are produced by either Sanger's enzymatic method or Maxam–Gilbert's chemical cleavage method, are separated by gel electrophoresis to achieve sequencing. With the use of MALDI for sequencing, the speed can be significantly greater than with gel electrophoresis. In addition, MALDI sequencing does not require labeling for identification, which saves both time and cost.

During the past few years, mass spectrometry for sequencing short DNA fragments has been pursued. In 1995, the first sequencing of a 45mer ss-DNA using MALDI-TOF with enzymatic preparation of DNA ladders was demonstrated. Recently, sequencing of ss-DNA higher than 100 nucleotides by using cycle sequencing to produce DNA ladders was achieved. Figure 7 shows the negative-ion mass spectra of DNA ladders from A, C, G, and T reactions using double-stranded DNA 130 bp as the template with reverse primer. Forward primers were also used for sequencing with results similar to the data shown in Fig. 7. Since sequencing by using both forward and backward primers

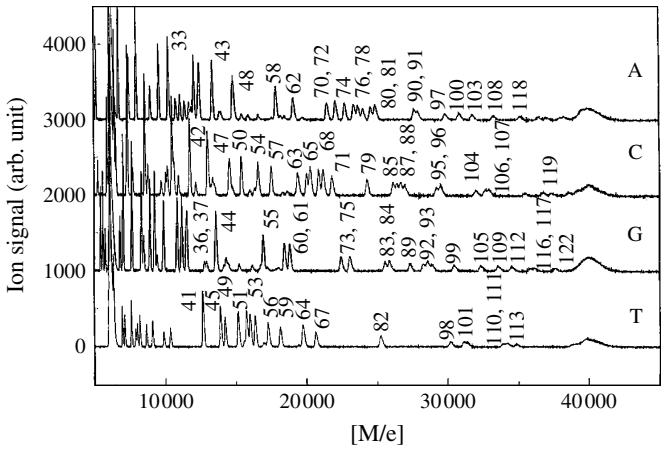

Fig. 7 Mass spectra of Sanger sequencing. DNA ladders were produced by dideoxynucleotide chain termination of the PCR product of a double-stranded template. Owing to the limitation of mass resolution (M/Δ M), the largest ss-DNA can be sequenced is limited to ~ 100 nt.

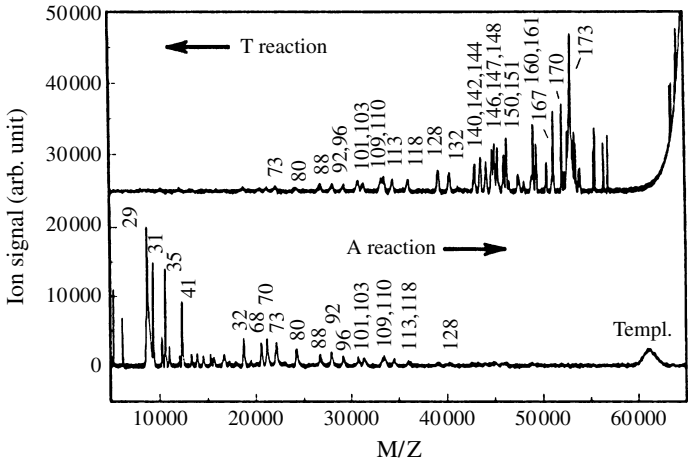

Fig. 8 Negative-ion mass spectra of Sanger sequencing. Ladders were produced by a dideoxynucleotide-chain termination of the PCR product of a double-stranded 200-bp template. The results were from the A- reaction with the reverse primer and T-reaction with forward primer.

can reach 120mer, complete sequencing of 200-bp DNA can be achieved. Figure 8 illustrates the idea of combining the spectra from forward and backward primers to sequence ds-DNA with a 200-bp template. Since mass is measured to identify the size of DNAs, there is no concern about a missing band, which can occur in the gel electrophoresis method. Thus, redundant sequencing can possibly be eliminated using MALDI DNA sequencing.

At present, automatic gel sequencers can read up to 1000 bp, but most routine sequencing ranges from 300 to 500 bases. Since the size of DNA to be sequenced by mass spectrometry is smaller than in the gel method, MALDI may not be an efficient method for *de novo* DNA sequencing for genome projects. However, with the sequencing of many different genomes completed, mass spectrometry is emerging as a useful tool for DNA resequencing due to its speed and the absence of a requirement for DNA labeling.

2.2.2 **Direct Sequencing**

When using mass spectrometry for sequencing DNA with ladders, the time needed for a TOFMS to separate and detect various ladders is only a few seconds. However, the time needed to prepare DNA ladders is many minutes to hours. Thus, the ideal sequencing method would be to use mass spectrometry to carry out direct DNA sequencing without the need to produce DNA ladders by chemical or enzymatic methods. This also implies that DNA ladders need to be produced during the laser ablation process.

Direct DNA sequencing can be easily understood from the illustrations in Figs. 9 and 10. Assuming the selective cleavage of P–O bond at 3′-linkage for an oligonucleotide of 5′-CTGTGA-3′, the primary fragmentation of such breaking of this bond will result in two series of fragments. These are labeled as 5′- and 3′-termini (Fig. 9). Each series has six members ranging from 1- to 6-mers. The vertical dotted line in Fig. 9 represents the position of the

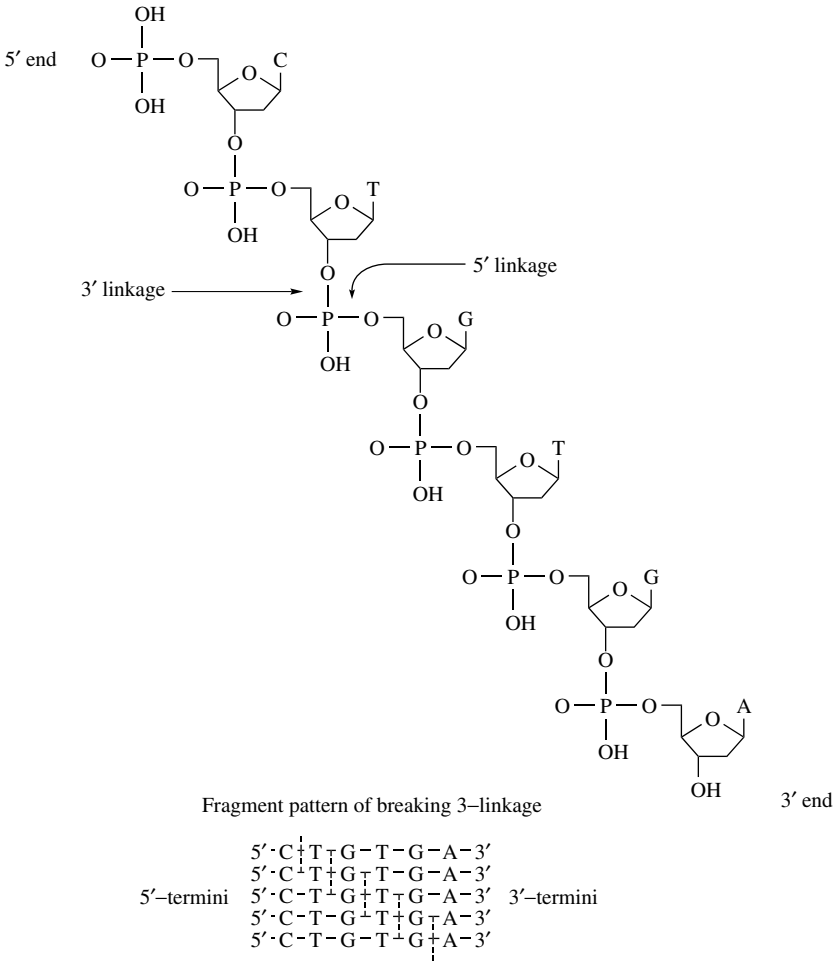

Fig. 9 Illustration of the selective cleavage P–O bond and the fragmentation pattern for a 5′-CTGTGA–3′ oligonucleotide.

cleavage. The fragments in both series can be ionized and resolved in MALDI spectra. Figure 10 shows the simulated mass spectra for these two series. Trace 'a' in Fig. 10 is the spectrum of the series with 3′-termini. The mass difference between two adjacent peaks in the series provides the information for each extra base. For example, the first member of this series is A, and the second member is GA. Owing to the selective cleavage of 3′-linkage, the mass difference between these two peaks will be exactly 329.2 daltons, which represents the mass of dGMP. The sequence information can be obtained by analyzing all values of mass difference in this series together with the total mass of 5′-CTGTGA-3′. The same information can also be obtained from the series with 5′-termini (Fig. 10, trace 'b'). If a complete series (either 5′- or 3′- termini) of such fragmentation for a DNA sample can be

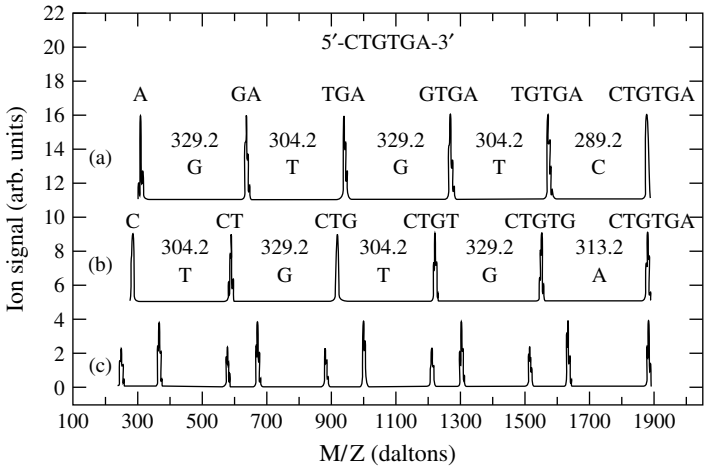

Fig. 10 Simulated spectra of the selective cleavage of P–O 3′-linkage for 5′-CTGTGA-3′ oligonucleotide: (a) simulated spectrum of fragment series with 3′-termini by the 3′-cleavage; (b) series with 5′-termini by 3′ cleavage; and (c) is the combination of (a) and (b).

experimentally resolved, the full sequence information will be obtained. Trace 'c' of Fig. 10 shows a mass spectrum of two series from the cleavage of 5'-linkage P–O bond. This sequencing method is very reliable since the sequence result from one series can be reconfirmed by the results from other series. Recently, UV-MALDI was attempted in order to achieve direct DNA sequencing by carefully adjusting the experimental conditions, which include the use of newly discovered two-component matrices and adequate laser fluence. Figure 11 shows the direct sequencing of DNA probes up to 35 nucleotides. Similar results by IR-MALDI and by electrospray high-resolution Fourier transform mass have also been reported. At present, direct sequencing is still limited to short oligonucleotides, owing to the limited mass resolution, since the mass difference between different bases needs to be identified. If a 60mer oligonucleotide is to be sequenced, the accuracy of the ion peaks needs to be better than 1 in 2000 since the mass difference between A (adenine) and T (thymine) is only 9 daltons. When a DNA segment is longer than 100mer, the effect of the abundance of ^{13}C isotope makes the distinction between A and T extremely difficult.

3
MALDI for Disease Diagnosis

DNA mutations that causes diseases can be simply classified into three major categories. These are (1) deletion or insertion, (2) point mutation, and (3) dynamic mutation. MALDI has been applied to all these different categories.

3.1
Base Deletion

In 1994, mutations in the cystic fibrosis (CF) gene in clinical samples were first demonstrated. Several measurements of CF were also carried out by mass spectrometry. In the North American

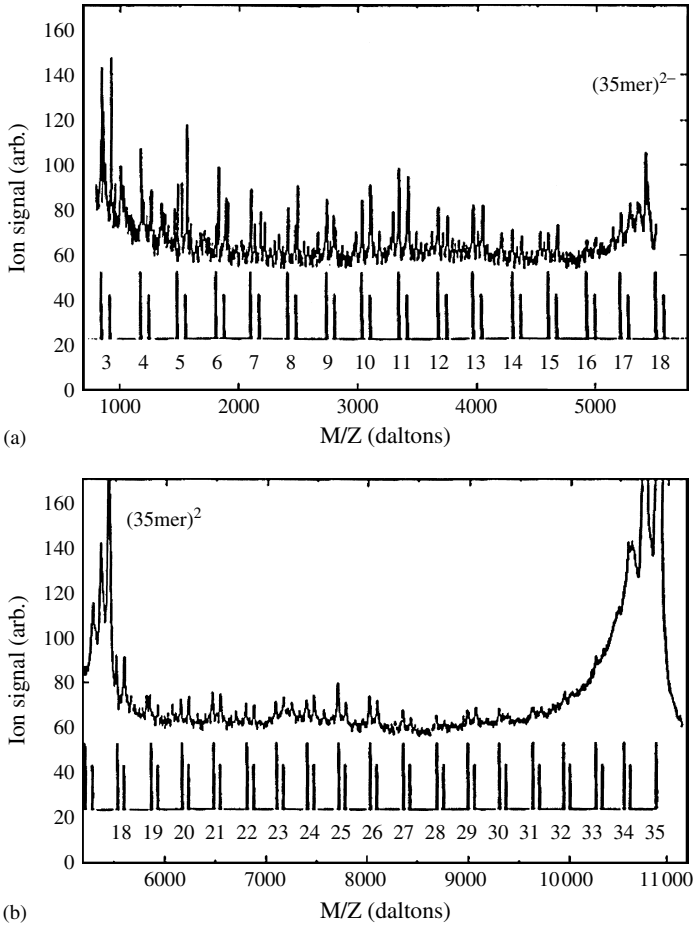

Fig. 11 MALDI mass spectrum with selective fragmentation for direct sequencing of a 35-nt oligonucleotide, 5′-GCGTGATGGAATCGATGACGTGCGATGTCGTGTTT-3′ The higher intensity series in the simulated spectra is 5′ termini and 3′ cleavage series and the lower intensity is 3′ termini and 3′ cleavage series. A mixture of 3-HPA and 2,4,6- trihydroxyacetophenone was used as a matrix. (a) and (b) are for low and high mass regions respectively.

population, about 70% of CF carriers have a 3-bp deletion in exon 10, resulting in the loss of phenylalanine residue at codon 508 (ΔF508). Two oligonucleotide primers, CF1 and CF2, were designed to amplify a DNA segment spanning the deletion, thus generating a 59-bp and 56-bp fragment of the normal CF gene and ΔF508 mutation, respectively (Fig. 12). Analysis of the PCR amplified products by MALDI resolved the 3-bp difference between the normal and the ΔF508 alleles in the spectra shown in Figure 12. To validate the efficiency of MALDI-TOFMS, a total of 30 genomic DNAs from patient samples were used as templates to amplify DNA segments

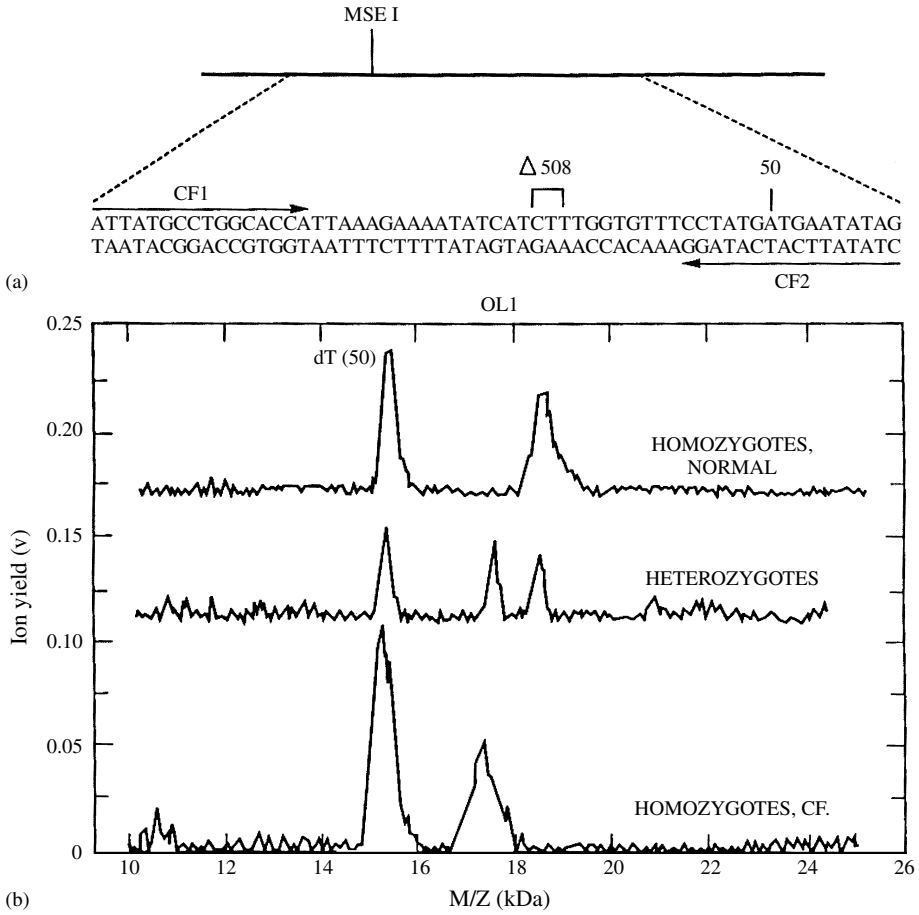

Fig. 12 Differential diagnosis of individuals with the normal and Δ F508 alleles by MALDI-TOF mass spectrometry. (a) Nucleotide sequence of 59 bp in exon 10 of the CFTR gene with the primers CF1 and CF2 indicated by arrows. A deletion of 3 bp in Δ F508 mutation is marked by the bracket. The DNA fragment amplified by PCR with forward and backward primers is schematically represented by the horizontal line on the top of the nucleotide sequence with a unique MseI site indicated. (b) MALDI-TOFMS of DNA amplified from a healthy volunteer, a Δ F508 carrier, and a CF patient. A synthetic dT_{50} was included as an internal standard for mass peak calibration.

from exon 10 or other exon/intron regions (as negative controls) of the CFTR gene. The samples were coded numerically and amplified by PCR. All the samples with ΔF508 mutations were verified earlier by size fractionation in a 10% acrylamide gel or by sequencing analysis. In a double-blind study (both PCR and mass analyses were performed without knowing whether the CFTR was normal or mutated), results from the mass spectrometry and conventional assays were in total agreement. These results indicate that MALDI mass spectrometry has the potential to become a valuable method of clinical CF diagnosis.

3.2 Point Mutation

Most DNA mutations due to contaminants are point mutations. Thus, the capability to detect point mutations by mass spectrometry is essential. MALDI has also been applied for point mutation detection. The approach is to amplify the desired region of a DNA template by PCR using two primers that have their 3'-ends extended to the site of expected mutation. To test this approach, a synthetic oligo with 60 nucleotides, whose sequence is derived from human p53 mRNA from codon 144 to 163, was used as a template with two normal allele-specific primers in a PCR (ASPCR). The lengths of the primers used were 16 and 23 nucleotides. By using a normal template and normal allele-specific primer pair, a normal PCR DNA product is expected to be produced. The size of the expected PCR product should be equal to the sum of both primers minus one. On the other hand, little PCR product will be made if the normal template is replaced with the mutant template, because the 3′-end base of normal primers results in a mismatch with the mutant template. Since Taq DNA polymerase lacks a 3′ exonucleolytic proofreading activity, the mismatch will block the amplification during PCR. The sequence of the template and the primers used were

Primer 1 (23mer)
5'-CAGCTGTGGGTTGATTCCACACC-3'
Template (60 bp)
5'-CAGCTGTGGGTTGATTCCACACCC
CCGCCCGGCACCCGCGTCCGCG
CCATGGCCATCTAC-3'
3'-GGGGCGGCCGTGGGC-5'
Primer 2 (16mer)

As shown in Fig. 13, the PCR products with the expected size of 38 nucleotides could be clearly observed. On the other hand, no PCR products were detected when the normal templates were replaced with mutant templates (Fig. 14). Since mutation of the p53 gene has been

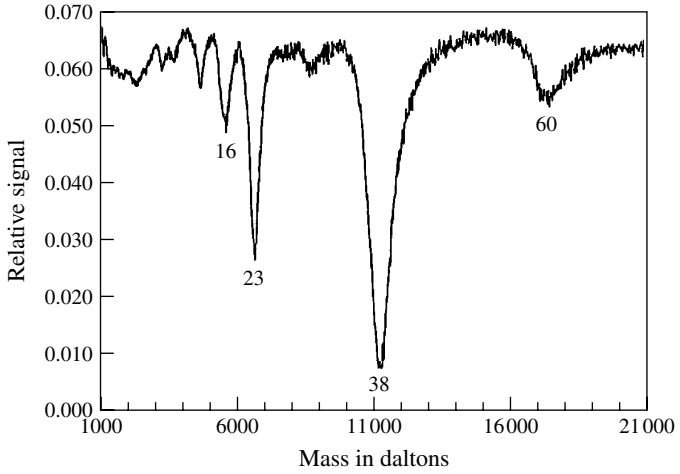

Fig. 13 MALDI mass spectrum of 38-bp PCR product with two primers overlapping at one base. The lengths of primers are 16 and 23 nucleotides.

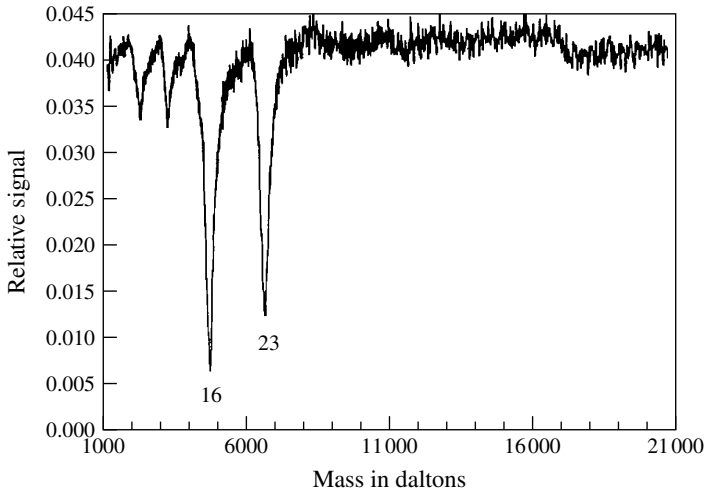

Fig. 14 MALDI mass spectrum with primers at the mutation site not complementary to the template. No PCR products, namely 38 bp were observed.

found to be responsible for more than 60% of cancers, the capability to detect p53 mutation is valuable for giving early warning of possible cancer development.

Measurements of G551D point mutation in cystic fibrosis transmembrane conductance regulator (CFTR) have also been attempted. The G551D mutation in the CFTR gene involves a G to A mutation, which results in a glycine to a spartic amino acid substitution. The approach is similar to the one adopted for point mutation in the synthetic template simulating a portion of the p53 gene. If the two primers based on the normal sequence match the target DNA sequence, a normal PCR product will be produced. However, if the alternate primers that match the mutant hybridize, a PCR product specific for mutant sequencing will be produced. Thus, the mass spectrometer can be used to identify people who are homozygous-normal, heterozygous, or homozygous-abnormal at a mutation site. A typical result is shown in Fig. 15. A heterozygous template was used. The peaks of 37 and 46 bp represent the PCR products from both normal and mutant plates. Four primers with different lengths were used in this work.

3.3 Dynamic Mutation

There are numerous genetic diseases such as Huntington's disease (HD), dentatorubral-pallidoluysian atrophy (DRPLA), Kennedy's disease, and a number of spinal–cerebellar ataxias, which are due to the abnormal trinucleotide expansion. Rapid measurements of the number of these trinucleotide repeats can give accurate identification of normal, heterozygous carrier, and homozygous patients. Examples of MALDI mass spectrometry for rapid diagnosis of Huntington's disease and DRPLA are given in Figs. 16 and 17.

From the above, it is clear that MALDI mass spectrometry can be used in the diagnosis of various diseases.

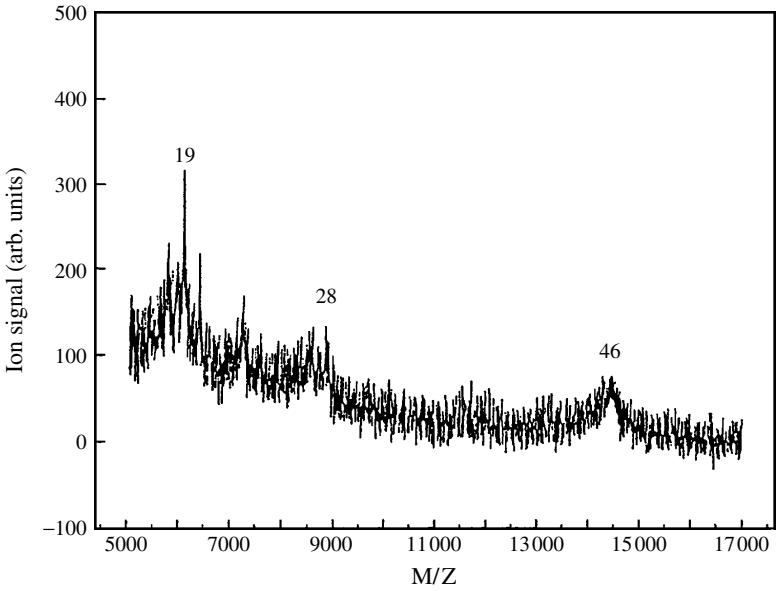

Fig. 15 MALDI mass spectrum for the detection of G551D point mutation in cystic fibrosis transmembrance conductance (CFTR). The G551D mutation in the CFTR gene involves a G to A mutation that results in a glycine to aspartic amino acid substitution. Mass spectrum of PCR products in 46 bp indicates the sample has a heterozygous template.

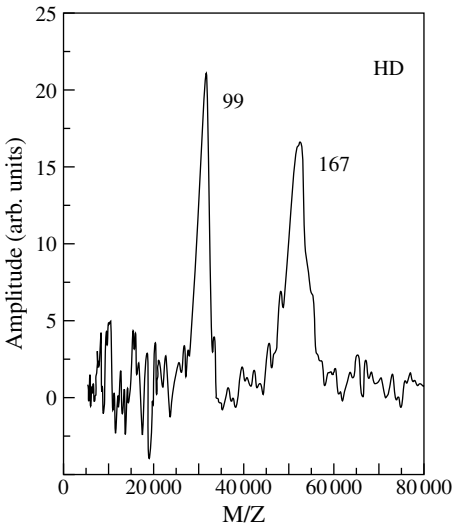

Fig. 16 Mass spectrum of a Huntington disease (HD) patient sample. Experimental results show the sample is heterozygous with CAG repeats of 17 and 40.

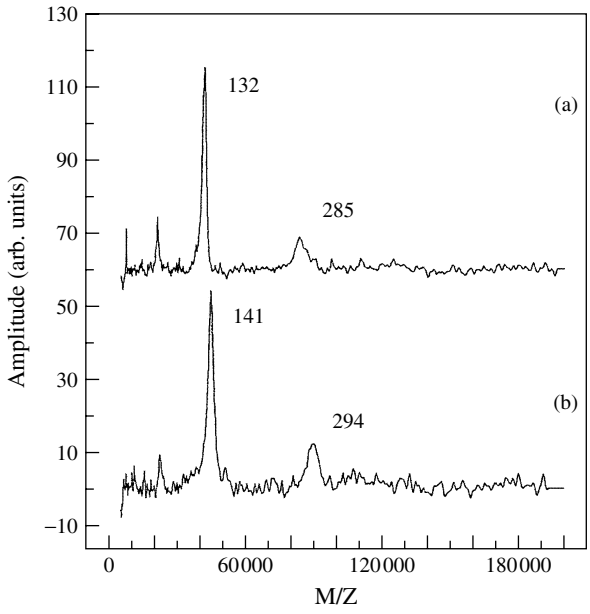

Fig. 17 Mass spectra for dentatorubral–pallidoluysian atrophy (DRPLA) patient samples. Both samples in (a) and (b) are heterozygous with the CAG repeats as 12/63 and 15/66 respectively.

4 DNA Typing for Forensic Applications

DNA fingerprinting is a technology that identifies individuals based on patterns of DNA markers detected in the genomic DNA. It can be used in forensic analysis to identify suspects or victims. It is particularly valuable at scenes of violent crimes where a body may not be available, or in instances where decomposition or dismemberment excludes the use of standard forensic techniques. There are several different approaches available to obtain DNA typing for forensic applications. These include restriction fragment length polymorphism (RFLP), short tandem repeats (STR), and single nucleotide polymorphism (SNP).

The foundation of DNA typing for person identification was established by the observation of restriction fragment length polymorphism (RFLP) in which polymorphic DNA loci are determined from restriction enzyme digestion. In 1985, Jefferys and his collaborators discovered that 33- and 16-bp repeated structures that vary in number between different individuals, referred to as *minisatellites*, could be used for fingerprinting. In 1987, the isolation and characterization of variable numbers of tandem repeats (VNTR) for single-locus DNA profiling was reported. More recently, the emphasis has shifted to the typing of STRs because of the high reliability arising from the large number of STRs in the human genome. During the past few years, it was discovered that SNPs) occur once every 300 to 1000 bp in DNA fragments. Thus, SNP typing is expected to become a very reliable tool for person identification in the future.

4.1
Forensic DNA Sample Preparation

In the process of using DNA typing for forensic applications, it is critically important to have very reliable and stringent protocols established. The major steps for DNA typing often include (1) Sample collection: blood, buccal cells, and hair follicles are the general sources for fresh DNA. For dried stains, samples should be collected and maintained in a dry, cool state. For autopsy tissue, it can be more reliable to have samples from more than one organ. All samples must be labeled as to source, tissue type, and the time and date of sample collection. (2) Storage and Transport: DNA samples can be stored and shipped as nonextracted tissue, as a lysate with tissue in an appropriate EDTA (ethylene diamine tetraacetic acid) solution, or as fully extracted pure DNA. For nonextracted tissues, sample refrigeration during shipping is often recommended. (3) DNA extraction: standard phenol–chloroform extraction and alcohol precipitation processes are often used to extract DNA from biological samples. An automated DNA extractor can achieve high quality extraction. It is desirable to complete DNA extraction as soon as possible. (4) DNA amplification: DNA amplification is often necessary to increase the quantity of sample available for analysis. PCR is the standard technique for the amplification of a selected DNA segment. Since an amplification of 10^6 or more can be achieved by PCR, any contamination by other DNAs can lead to a false conclusion. Thus, great care must be taken to prevent cross-contamination of sample material at the collection site and at any time during the analysis. (5) DNA size or sequence determination. This is the ultimate step leading to the conclusion of person identification. Until now, gel electrophoresis has been used for both DNA size determination and sequencing. However, analysis by mass spectrometry can be faster and more reliable.

The primary goal of DNA profiling for forensic application is to get the assurance of a match (inclusion) or mismatch (exclusion) of the evidence DNA sample with the suspect or victim's sample. In general, DNA profiling can be used to easily *rule out* the suspect when DNA typing between suspect and evidence shows clear differences. Thus, DNA typing is a very powerful tool for proving that an individual *does not* match the DNA collected at a crime scene. On the other hand, if the DNA profile from the evidence sample matches with the suspect, there is still a possibility that the evidence DNA could have come from another person. It might be a coincidental match between two persons having similar DNA profiles. Thus, population genetics plays an important role in suspect identification. The simplest approach is to assume that mating is random. The random mating of persons produces the same genotypes as random combinations of sperm and egg. Although the mating in local populations is not usually strictly random, the random match model provides a good approximation when no special genetic linkage is involved. For subpopulation groups such as people in an isolated village, the random mating approach is not generally a reliable assumption. However, it can probably be used as a guide for the minimum number of loci to be analyzed for confirming the matching of the suspect with the evidence.

Since the confirmation of matching the suspect with the evidence DNA often requires the analysis of several loci, the time

needed for DNA profiling can be long and the cost, high. At present, all forensic DNA samples for court evidence are analyzed by gel electrophoresis. Visualization of DNA in this procedure requires the use of either radioactive material or dye tagging. VNTR electrophoretic analysis, especially with radioactive probes, can take several weeks to complete the analysis of different loci for forensic confirmation. The human factor introduced by lengthy handling increases the risk of error or contamination and reduces reliability.

4.2 Mass Spectrometry DNA Detection for Forensic Applications

Each DNA typing involves (1) measurements of DNA fragments associated with genetic markers; (2) match determination for various genetic markers for different samples; and (3) statistical analysis for the type match to determine the possibility of an accidental match. All sequencing or size determination of DNA fragments for forensic applications to date have been carried out using gel electrophoresis. The various approaches among the forensic community include the analysis of VNTR, STR, SNP, and DNA sequencing. Laboratory protocol and standard procedures for data analysis were set up for forensic sample analysis. With the recent progress in development of mass spectrometry for DNA analysis, there is a good potential for the use of mass spectrometry for all the above applications. Since the use of mass spectrometry for DNA analysis is still in the early stages of development, standard protocols for its use in forensic analysis have not yet been established. The potential applications of using mass spectrometry in DNA fingerprinting for forensic applications is presented and discussed below.

4.2.1 RFLP and VNTR Analysis

DNA typing relies on the use of DNA markers. Among the most widely used DNA markers are restriction fragment length polymorphisms. RFLP analysis is based on differences in the positions of restriction endonuclease recognition sites. Restriction endonucleases are enzymes, which recognize and cut double-stranded DNA at sequence-specific recognition sites. Homologous DNA fragments from different individuals will contain different cut sites based on random mutations within the stretch of nucleotides. Consequently, fragments differing in length and number will be generated upon restriction digestion. These constitute RFLPs, and because they differ in size, the RFLP fragments can be readily separated by routine agarose electrophoresis.

When an individual's entire genomic DNA is digested by a restriction endonuclease, hundreds to thousands of restriction fragments are produced. When digested genomic DNA is subjected to gel electrophoresis, individual bands are not discernible. In such a case, analysis is generally facilitated by the Southern blotting technique. In Southern blotting, digested DNA is separated by electrophoresis. The digested fragments are transferred to a nitrocelluose or nylon membrane through capillary action. The DNA binds to the membrane by electrostatic attraction. Labeled probes specific for the RLFP of interest are then hybridized to the DNA-containing membrane. A banding pattern can be visualized using autoradiography or chemical detection techniques. Each individual will exhibit a characteristic pattern. Several RFLPs must be used

to statistically ensure that an individual's pattern is unique. The fact that RFLPs can occur anywhere in the genome and that there are potentially millions of RFLPs detectable with different probes makes RFLP analysis a tremendously powerful tool for forensic use.

A special class of RFLPs is based on DNA sequences that occur in tandem repeats. Tandem repeats arise when slippage mutation occurs during DNA replication. It has been observed that this type of mutation occurs frequently enough to generate significant variations over many generations. Polymorphism for these markers is so high in humans that only identical twins will have the same patterns. This factor makes the use of tandem repeats analysis extremely valuable to forensic scientists.

Variable number tandem repeat (VNTR) analysis has been used extensively in forensic applications. VNTRs consist of approximately 10 to 100 bp repeated several times in tandem. For example, a tandem repeat of the trinucleotide CTG would appear in the genome as CTGCTGCTGCTGCTGCTG. In this particular example, this sequence has seven repeats. VNTRs are generally bordered by unique sequence DNA, a characteristic that can be exploited by current technology. In VNTR analysis, genomic DNA is digested with a restriction endonuclease that does not contain a cut site within the tandem repeat sequence. Since the restriction enzyme cuts outside of the tandem repeat region, the tandem repeat is left intact. Tandem repeat fragments are separated by gel electrophoresis and analyzed with Southern blotting. The length of the tandem repeat will vary between individuals. Individuals can be homozygous or heterozygous for a particular VNTR. The large number of VNTR-containing loci creates millions of possible pattern combinations. If there are n loci, there should be n homozygotes and $n(n-1)/2$ heterozygotes. If m loci are analyzed, the number of possible genotypes is $[n(n+1)/2]^m$. If $n = 20$ and $m = 4$, there are more than 1 billion genotypes. As a result, VNTR provides the forensic analyst a powerful tool for inclusion and/or exclusion.

The need for Southern blotting can be eliminated if the VNTR region is selectively amplified with the polymerase chain reaction (PCR). PCR primers complementary to sequences flanking the tandem repeat region can be designed and used to amplify the tandem repeat region. The length of an individual's tandem repeat can then be obtained by gel electrophoresis. It is PCR amplification of VNTRs that shows a lot of promise for MALDI detection. By using MALDI for RFLP detection, gel electrophoresis, Southern blotting and radioactive material or dye tagging can be eliminated. Figure 18 shows the mass spectra for restrictionenzyme–digested DNA samples. A difference of 12 bases with three 4-base tandem repeats can clearly be observed. Both primary and doubly charged ion peaks are observed. The spectrum indicates that one chromosome in this region is 12 bp longer than the same region in the other chromosomes. Thus, the result indicates the sample is from a person with heterozygous vWFII.

4.2.2 **Short Tandem Repeats (STR)**

For VNTR analysis by measuring RFLP without the use of PCR, one major disadvantage is that the quantity of the DNA sample is so small that a long analysis time is required. One promising alternative is to amplify and measure loci containing short tandem repeats (STR).

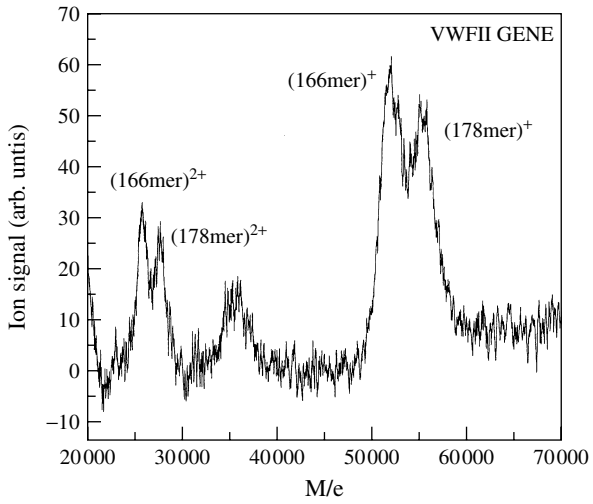

Fig. 18 Mass spectrum from the digestion of a part of *vWFII* gene. Peaks are observable for a difference of 12 bases. Both primary and doubly charged ion peaks are observed. The spectrum indicates that one chromosome in this region is 12 bp longer than the same region in the other chromosome.

There is a large number of STR distributed throughout the human genome. STR analysis can be used for as many loci as are needed for reliable identification. PCR is nearly always used in STR analysis. Since PCR can amplify the selected DNA segments by more than six orders of magnitude, only a very small quantity of DNA sample is required. However, the disadvantage is that any procedure using PCR amplification is highly susceptible to contamination. Even a trace of foreign DNA contamination can be amplified and detected to potentially lead to a false conclusion. However, careful handling of DNA samples or applying quantitative PCR techniques can more or less resolve the concern regarding DNA contamination. Since the analysis of STR is by measurement of the sizes of DNA products from the PCR process, the sizes of the DNA fragments are often less than 300 bp and the quantity is often in the range of a few picomoles, which can be readily detected by MALDI.

Typical mass spectra of a DNA sample amplified by PCR from parts of different genes are shown in Fig. 19. Since different people have different numbers of repeats in each of these genes, measurements of the number of repeats for several loci can be used for person identification. There are many tetranucleotide repeats, which can be used for forensic identification. HUMTH01 is one that is often used in forensic applications.

4.2.3 Single Nucleotide Polymorphism (SNP)

There are several types of DNA sequence variation, including deletion, insertion, difference in number of repeats such as STR and single base-pair differences. The single base difference is the most common type. This single base pair difference is often referred to as *single nucleotide*

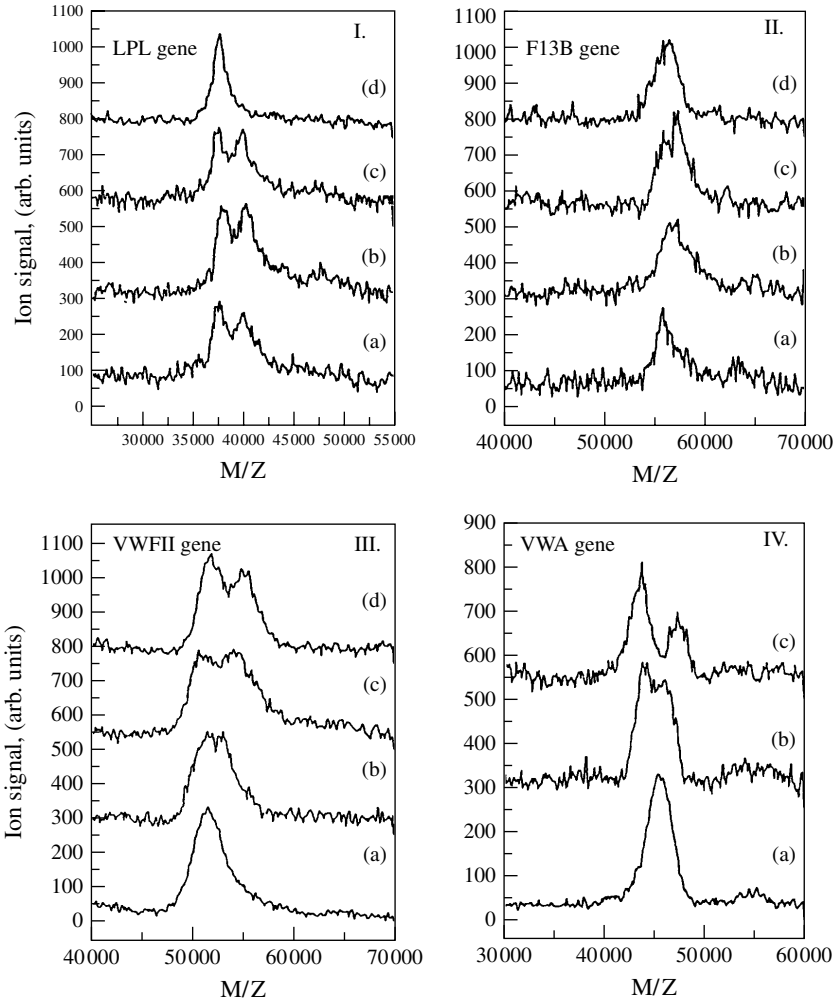

Fig. 19 MALDI mass spectra of PCR products of *LPL*, *F13B*, *vWFII*, and *vWA* genes from different persons. Homozygous and heterozygous as well as the number of the short tandem repeats can be determined. This indicates MALDI can be used for short tandem repeat determination for forensic applications.

polymorphism (SNP). There are several million SNPs in the human genome. The predominance of SNPs and their much lower mutation rate make SNP analysis extremely valuable for forensic applications. ASPCR, described above for point mutation detection, can also be applied to SNP detection.

Another approach to using MALDI for SNP detection is to hybridize a primer adjacent to the polymorphic locus and extend it by a single base by dideoxynucleotide addition. MS can be used to accurately measure the mass of the extension product to identify the base. For homozygotes, one peak will be observed.

However, two peaks should be observed for a heterozygote.

4.2.4 **Gender Determination**

Sex determination is often important for identifying suspects and victims. A reliable gender test is PCR amplification of a segment of the X–Y homologous gene amelogenin. A single pair of primers spanning part of the first intron generates 106-bp and 112-bp PCR products from the X and Y chromosomes respectively. MALDI can be subsequently used for the measurements of PCR products. Recently, it was found that the deletion of the Y-encoded gene occurs in a small percentage of Y chromosomes. Thus, it is more reliable to test both amelogenin and the male sex-determining gene SRY for gender determination. Male DNA generates three products of lengths 93 bp (SRY), 106 bp (Amelogenin in X chromosome) and 112 bp (amelogenin in Y chromosome). Coamplification of female DNA generates only the 106-bp product. As shown in Fig. 20, the distinction of genotyping between male and female is quite clear. Figure 20 shows examples of mass spectra of PCR products for (a) female gender, (b) male gender, and (c) mixture of male and female gender. Of special interest in forensic analysis, especially for sexual assault, is the detection of a trace amount of male-specific DNA in a female sample. Such detection can be performed by demonstrating the presence of male-derived products of 93 bp and 112 bp. When MALDI spectra of a composite sample containing mostly female species (10 ng) and only a trace amount of male sample (0.01 ng) was checked, the trace of the male sample could be detected. It

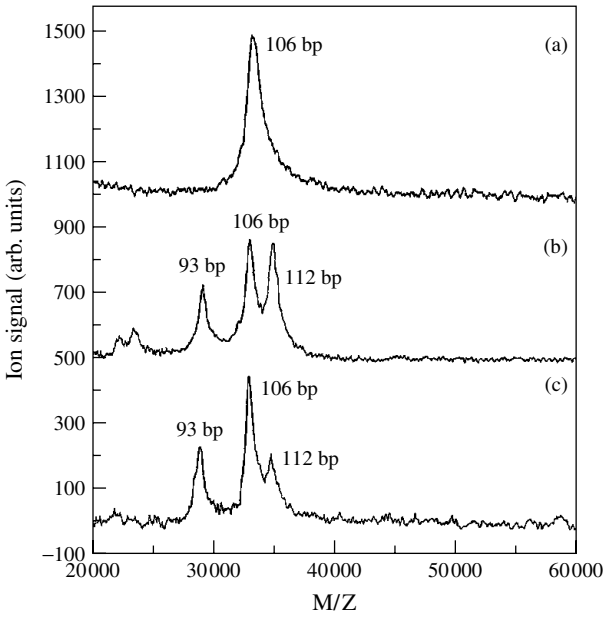

Fig. 20 Mass spectra of samples for sex-specific coamplification (Amel X/Y plus SRY) of loci for (a) female (b) male, and (c) female plus male (with sample ratio of 1 : 1) respectively.

indicates that as little as 0.1 percent of male DNA in a female DNA sample can be detected. It also indicates that the detection sensitivity can reach 0.01 ng or less which is about one order of magnitude better than by gel electrophoresis.

5 Conclusion

Mass spectrometry provides a unique method of nucleic acid detection and sequencing. Applications relating to disease diagnosis, and forensic applications in person identification have been clearly demonstrated. However, improvement in mass resolution and detection sensitivity of large DNA fragments is still required in order to enable MS to be routinely used for broad applications. A better understanding of the mechanisms of desorption and ionization will provide the basis for further improvement of MALDI.

Keywords

2D Page
Two-dimensional polyacrylamide gel electrophoresis; a technology that separates intact proteins according to their pI in the first dimension and molecular weight in the second.

MS/MS
A mass spectrometry technique in which precursor ions are selectively fragmented, thus allowing detailed structural information to be obtained.

MudPIT
A multidimensional protein identification technology; a proteomic method based on liquid chromatography of peptide mixtures with subsequent identification by tandem mass spectrometry.

Quantitative Proteomics
A group of methods that allow large-scale quantitative assessment of protein expression and identification.

Proteomics aims to identify, characterize, and map gene functions at the protein level for whole cells or organisms. A typical experimental scheme for a large-scale proteomics inquiry involves fractionation of a complex protein mixture by electrophoretic or chromatographic means followed by subsequent identification of the components in the individual fractions by mass spectrometry. Owing to

continuous and rapid improvement in instrument sensitivity, throughput capacity, software versatility, and techniques of statistical validation of the data, mass spectrometry–based approaches are becoming mainstream methods in a proteome analysis.

1 Principles and Instrumentation

1.1 Proteome and Proteomics

The term *proteome* was first introduced in mid-1990s to name the functional complement of a genome. By analogy with *genomics*, the term *proteomics* refers to studies of a gene's function at the protein level. Both these terms have a large-scale flavor to them. Indeed, studies that fall under the category ''proteomics'' frequently deal with large-scale analyses of proteins on the level of the whole organism, tissue, cell, or subcellular compartments.

Examples of typical biological questions addressed by modern proteomics experiments include but are not limited to establishing ''news of difference'' between healthy and pathological states, monitoring global gene expression during growth and development, establishing cellular localizations of a particular subset of an expressed genome, and identifying networks of protein–protein interactions. In fact, a recent review classifies proteomics studies according to the type of the addressed biological questions into ''profiling proteomics,'' ''functional proteomics,'' and ''structural proteomics.'' Profiling proteomics amounts to large-scale identification of the proteins in a cell or tissue present at a certain physiological conditions. Functional proteomics refers to the studies of functional characteristics of proteins – posttranslational modifications, protein–protein interactions, and cellular localizations. Structural proteomics includes studies of protein tertiary structure, typically made by a combination of X-ray, NMR, and computational techniques. Adopting this classification, this chapter primarily focuses on the profiling and functional proteomics.

1.2 Need for Large-scale Analyses of Gene Products at the Protein Level

Rapid success of the various genome-sequencing programs is one of the major factors that led to the development of large-scale proteomics methods. In fact, a search of the genome-derived sequence databases is usually an intrinsic part of mass spectrometry–based proteome analysis. While of tremendous value, genomic information is, in principle, insufficient for understanding the complex processes of cellular function. Indeed, in addition to the projection of the information from genes into proteins, cells of the living organisms must metabolically extract useful information from the environment. Therefore, the total informational content necessarily increases in a proteome compared to the corresponding genome.

An immediate consequence of this increase in the informational content is that all of the following – protein isoforms, protein posttranslational modifications, protein conformational states, protein abundance levels, as well as dynamical

changes of these properties – have their own important functional implications in the living cells. In certain cases, genomic sequence still can be used to assess some of the functional properties of the corresponding proteins. For example, the codon adaptation index (CAI) and codon bias can be used to predict the expression level of genes. Another important case is a global sequence-based prediction of protein–protein interactions, an example of which is discussed in Sect. 3 of this chapter.

Also, to some degree, the functional properties of proteins can be assessed by analysis of the mRNA transcripts. Specifically, mRNA expression profiles are frequently used to estimate the corresponding protein levels. Most common methods that are used to measure global mRNA expression are cDNA microarray and serial analysis of gene expression (SAGE). However, in many cases, the correlation between mRNA and protein is insufficient to quantitatively predict protein expression. Potential reasons for these discrepancies in mRNA and protein levels include the differences in half-lives of proteins and mRNAs and posttranslational mechanisms that control the rates of translation. Thus, neither DNA nor mRNA sequence information is sufficient for understanding of the cellular functions. This fact provides motivation to improve the old and develop new technologies for the large-scale analyses of gene products at the protein level.

1.3 General Problems in Proteome Analyses

In a given organism, there are several times more different proteins than there are genes. Estimates for humans give such numbers as about 30 000 different genes and more than 100 000 different proteins. Factors such as posttranslational modifications, isoforms, and expression levels increase the complexity and interconnectedness of a proteome compared to a genome. Problems associated with modern proteomics methods include (1) difficulties in the detection of low-abundant proteins; (2) difficulties in obtaining quantitative information; (3) biases in a proteome coverage; (4) difficulties in characterization of posttranslational modifications; (5) difficulties in data analysis and interpretation in the large-scale experiments; (6) poor reproducibility.

1. Protein levels as low as several dozens copies per cell can be of functional significance. This is true for certain receptors, signaling proteins, and regulatory proteins. However, detection of the low-abundance proteins is often an issue in proteomics experiments. The ability of a proteomics method to identify low-abundant proteins in the presence of high-abundant ones is characterized by the dynamic range of a method. The dynamic range of a proteomics method is defined as the ratio of concentration of the most abundant to the concentration of the least abundant proteins identified by a method. Proteomics methods based on two-dimensional polyacrylamide gel-electrophoresis (2D PAGE) separations typically have a lower dynamic range than the methods based on affinity separation or multidimensional liquid chromatography.
2. Quantitative information on the protein abundance in different physiological contexts is the goal of comparative proteomics studies. 2D PAGE methods are good at solving these types of problems, when combined with scintillation

counting or fluorescence imaging spectroscopy. In the MS-based methods, quantitation is achieved by differential labeling (discussed in detail in Sect. 2).

3. Biases in proteome coverage can be inherent to a particular method, or be related to the design of an experimental scheme. For example, 2D PAGE methods are biased against highly hydrophobic proteins. At the same time, there is no inherent bias against hydrophobic proteins in MS identification. However, sample enrichment or fractionation steps necessarily preceding MS analysis are often biased against one or the other class of proteins.
4. Information on types and degrees of posttranslational modifications and protein isoforms is a necessary component of comprehensive functional description of a proteome. Unfortunately, it is difficult to design a proteomics method that would simultaneously give both good proteome coverage and identify all posttranslational modifications. Methods, such as 2D PAGE, which separate intact proteins, are good at the detection of different posttranslational modifications and isoforms present at the same time. However, owing to large diversity in protein masses and shapes, biases in proteome coverage are inherent in the intact protein methods.
5. During a large-scale proteome analysis, thousands of data points are generated. Hence, there are inherent problems related to the data reduction and extraction of the useful information. Additionally, the obtained information needs to be presented in an accessible format to the scientific community. These issues often require significant computational support and software development.
6. Most of the high-throughput, large-scale methods suffer from poor reproducibility. This is especially true in the case of 2D PAGE and MS-based schemes with several fractionation and separation steps involved. Possible ways to improve reproducibility include reduction in the number of separation and fractionation steps, adhering to standard protocols, and use of automation whenever possible.

Most of these challenges, however, are merely technical limitations. Modern technologies continuously progress toward higher sensitivity, higher range of proteome coverage, and higher reproducibility. Also, even if it may be impossible to have 100% proteome coverage with a single method, proper design of a proteomics program that takes advantage of several different methods can achieve impressive results.

1.4 MS Instrumentation

Mass spectrometry (MS) is a platform technology for all proteomics. It is the mass spectrometer that is used to identify the protein present in samples. Furthermore, there are a variety of mass spectrometry approaches that can be used to achieve this end. Figure 1 illustrates the general concept of MS analysis in proteomics. Generally, MS analysis involves creation of gaseous ions from an analyte followed by separation of the produced ions according to their mass-to-charge ratio (m/z). Instruments that perform analysis of this type are called *mass spectrometers*. Principle components of a mass spectrometer are an ion source, where ionization takes place; a mass analyzer, where the m/z is measured; and a detector, where amount

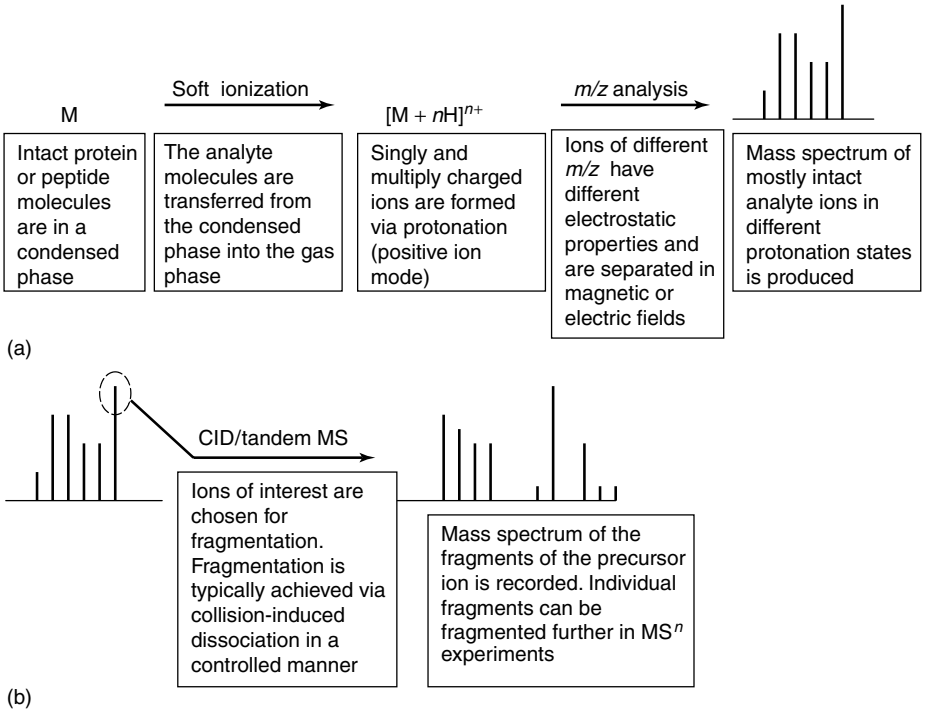

Fig. 1 Principle scheme of single MS (a) and MS/MS (b) analyses. (a) Intact proteins or peptides are transferred from the condensed phase into the gas phase and are ionized through capture (positive mode) or loss (negative mode) of protons. In high-throughput protein identification experiments, positive mode of ionization is used. Negative mode of ionization can be used for analysis of carbohydrates and nucleic acids. Ions of different m/z are discriminated by magnetic or electric fields. (b) Ions whose structure needs to be determined are chosen for fragmentation via CID reactions in the MS/MS experiment. The obtained fragmentation patterns can be searched against protein databases for identification.

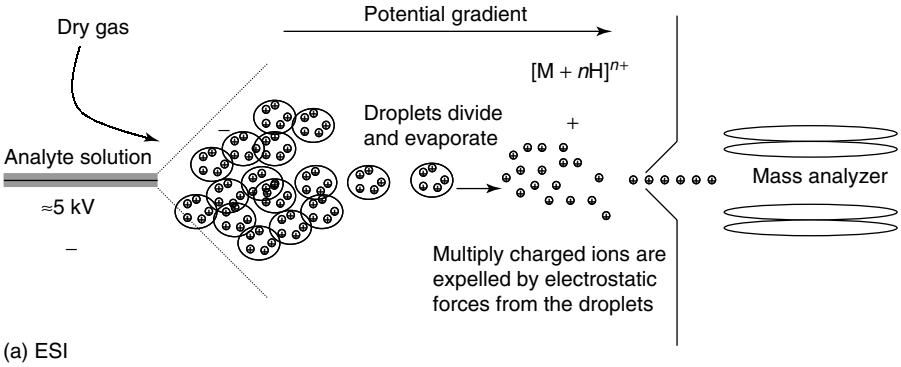
of the ions corresponding to a particular m/z is recorded. Large macromolecules, such as proteins, are nonvolatile, and owing to a lack of proper ionization techniques for a long time, MS was limited to the analysis of smaller molecules. Finally, in the 1980s, protein ionization methods were developed, thus making MS-proteomics feasible.

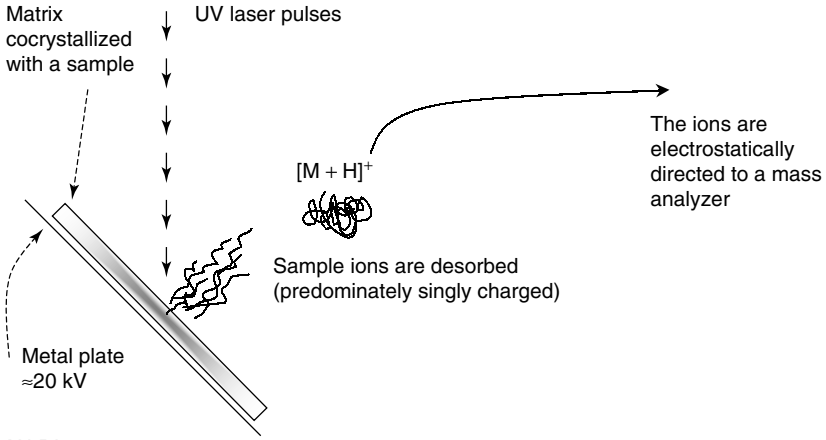
1.4.1 Ionization Methods

The two most commonly used methods of protein ionization are electrospray ionization (ESI) and matrix-assisted laser desorption ionization (MALDI). In both of these techniques, ionization occurs through uptake (positive mode) or loss (negative mode) of one or several protons. In large-scale proteomics studies, the positive mode is typically used. The negative mode of ionization finds its uses in analyses of carbohydrates and nucleic acids. In any of the available ionization methods, there is no definite relationship between the amount of ions formed and the amount of the analyte. This fact makes mass spectrometers inherently nonquantitative devices.

ESI produces mostly multiply charged ions by creating a fine spray of charged droplets in a strong electric field. With the application of a dry gas, the droplets evaporate, and the electrostatic repulsion causes transfer of the analyte ions into the gas phase (Fig. 2a). The multiple charging allows analysis of very large molecules with analyzers that have relatively small m/z range. Another advantage of the multiple charging is that more accurate molecular weight can be obtained from analysis of the distribution of multiply charged peaks. ESI is used in a wide range of proteomics applications but is limited by susceptibility to high salt concentrations and to contaminants in the sample.



(a) ESI



(b) MALDI

Fig. 2 Conceptual schemes of (a) Electrospray ionization (ESI) and (b) Matrix-assisted laser desorption ionization (MALDI). (a) During ESI, a fine spray of charged droplets is created. The droplets evaporate and the multiply-charged ions are expelled by electrostatic forces. ESI is frequently used for analysis of complex peptide mixtures via coupling to multidimensional liquid chromatography. (b) During MALDI, the analyte molecules are ejected by laser pulses from the sample cocrystallized with a matrix. During MALDI, mostly singly charged ions are produced. Because the analyte molecules are ejected in bundles, MALDI method is ideally suited for coupling to TOF mass analyzers. MALDI-TOF instruments are frequently used to analyze individual spots on 2D PAGE.

MALDI produces predominately singly charged ions by aiming laser pulses at a sample cocrystallized with a molecular matrix on a metal plate under high voltage (~20 kV). Typical matrices used in MALDI-assisted protein analysis include α-Cyano-4-hydroxycinnamic acid and 2-(4-Hydroxyphenylazo)-benzoic acid. The laser is tuned to the absorption maximum of the matrix. The sample ions are preformed in the condensed phase in sufficient quantities. The matrix absorbs some of the laser pulse energy, thus minimizing sample damage. The sample ions and matrix molecules gain enough kinetic energy and are ejected into a gas phase (Fig. 2b). Table 1 outlines and compares principle characteristics of these ionization methods.

Importantly, in both the MALDI and ESI sources, ion fragmentation occurs rarely and the analyte molecules remain largely intact. This nondestructiveness is what makes these methods so attractive for characterization of biomolecules. However, in certain applications (e.g. peptide sequencing), it may be necessary to fragment molecular ions (preferably in a predictable manner) in order to extract additional information. This is typically achieved via collision-induced dissociation (CID). Such types of MS analysis are called *tandem MS* (MS/MS) and often are denoted by MS^n, where n is the number of generation of fragment ions analyzed (Fig.1).

1.4.2 Mass Analyzers

Mass analyzers separate ions according to their m/z in electric or magnetic fields. Most common types of mass analyzers used in proteomics research are quadrupole (QD), ion trap (IT), time-of-flight (TOF), and Fourier transform ion cyclotron resonance (FTICR). Often in modern instruments, several analyzers of the same or different types are combined together to achieve maximum performance.

Tab. 1 Comparison of ESI and MALDI sources.

	ESI	*MALDI*
Principle of action	Uses electric field to produce sprays of fine droplets; as the droplets evaporate, ions are formed	Uses laser pulses to desorb and ionize analyte molecules cocrystallized with a matrix on a metal surface
Ions formed	Multiply charged (The larger the analyte molecule, the more likely it acquires multiple charges)	Singly charged
Mass range	>100 kDa	>100 kDa
Resolution	~2500 (with IT/QD mass analyzers)	~10 000 (with TOF mass analyzers and ion reflectors)
Typical application	10^{-15} mole LC/MS of peptide mixtures; tandem MS; protein identification by comparing experimental MS/MS spectra with theoretical MS/MS spectra produced from protein databases	10^{-15} mole Analysis of spots on 2D PAGE; determination of molecular weight; protein identification by ''peptide mass fingerprinting''

QD mass analyzers are frequently used in conjunction with ESI source. They offer moderate resolution (up to 2500 mass units) and moderate sensitivity. QD consists of four parallel rods with a hyperbolic cross section. Diagonally opposite rods are connected to radio frequency and direct-current voltage sources thus establishing the quadrupole field. Ions that are produced at an ion source are electrostatically accelerated into this quadrupole field. Mass-selection is achieved by proportional changes of amplitudes of radio frequency and direct current in a way that for any given pair of these amplitudes there, only the ions of specific m/z reach the detector. QDs are known for their tolerance of high pressures (up to 10^{-4} torr), which makes them attractive to use with ESI for liquid chromatography (LC)-coupled applications.

IT mass analyzers work by confining ions to a small volume via radio-frequently oscillating electric fields. ITs offer moderate sensitivity at a relatively low monetary cost and are good for MS/MS applications. In the latter case, ITs are often used cojointly with QDs. Mass accuracy of regular ITs is rather low, since only limited amount of ions can be accumulated in a small volume. Mass accuracy, as well as resolution can be significantly improved by using two-dimensional ITs (sometimes also called *linear*), which increase the ion storage volume.

TOF mass analyzers measure the time traveled by an ion from a source to a detector. The longer the flight path, the better the resolving power. However, longer flight paths also increase the scan time. In commercial TOF analyzers, compromise is achieved with the length of the flight path on the order of several meters. The resolving power of a simple TOF analyzer is poor – several to ten times less than that of QD. Significant improvement in the resolving power of TOF is offered by additions of one or several ion reflectors. Upon reflection, the velocity distribution of ions at particular m/z narrows, thus increasing resolution and sensitivity. As a result, modern TOF and double-TOF spectrometers can achieve resolving power of 10 000 and more. Measurement of the ion's TOF can be achieved only if the analyte ions are presented to TOF analyzer in discrete bundles. Because of this need for discrete ion bundles, TOF analyzers are particularly suited to the pulsed nature of MALDI. In fact, MALDI-TOF is one of the most common types of mass spectrometers used in proteomics research.

FTICR mass analyzers are based on the resonance absorption of energy by ions that precess in a magnetic field. The recorded array of the precession time-curves is Fourier-transformed to obtain the component frequencies of the different ions. Next, the component frequencies are related to the ion's m/z. Because frequency is a parameter that is easy to measure with high precision and accuracy, FTICR has the highest resolving power amongst MS analyzers – up to 10^6 and more. With FTICR, it is also particularly easy to do MS^n experiments. Unfortunately, current FTICR instruments are cumbersome, expensive, and not readily available.

1.4.3 MS/MS

In some applications, it is necessary to fragment molecular ions produced by ESI or MALDI further to obtain additional structural information. Figure 3 illustrates a possible way to do this with a triple–QD ESI mass spectrometer. To obtain a tandem spectrum, the first quadrupole scans across a set m/z range and selects ions of interest. In the second quadrupole, CID

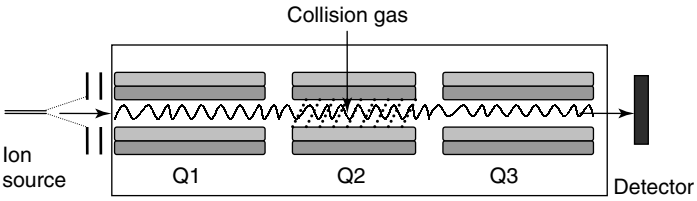


Fig. 3 A triple quadrupole mass spectrometer with MS/MS capability. Q1 selects ion to be fragmented and allows the selected ion to pass into Q2. The ions in Q2 are fragmented via collisions with inert gas (typically argon). Q3 analyzes the fragments generated in Q2. MS^n ($n \leq 4$) experiments can be performed with this setup as well. To achieve this, fragmentation must be increased at the level of ionization. In modern instruments, quadrupole-ion trap mass analyzers are used for MS^n ($n > 8$) experiments.

reaction takes place – ions that were selected by the first quadrupole undergo collisions with argon gas and fragment. Finally, the third quadrupole analyzes the resulted fragments. Importantly, the fragmentation via CID occurs in a predictable manner – protein and peptide ions break mostly at peptide bonds – which makes the large-scale sequencing easier.

1.5 Methods of Sample Fractionation

The large complexity of protein mixtures from biological samples poses additional challenges for proteomics experiments. Depending on the scope of a particular proteomics task, it is desirable to introduce sample enrichment and fractionation steps prior to MS identification. The scope of a particular task can range either from an analysis of a subset of a proteome – for example, analysis of proteins specific to a particular organelle and proteins modified in a certain way – to a simultaneous analysis of all the proteins in the proteome. In both of these cases, a proper choice of separation strategy determines the overall throughput and sensitivity of the proteomics experiment. While it may be desirable to fractionate protein mixture down to individual proteins (aim of 2D PAGE separation), significant gain in the throughput can be achieved when mixtures of proteins are introduced to the mass spectrometer.

MS analysis of intact proteins is impractical in most of the high-throughput tasks with the current instrumentation because of the large range in protein masses. To simplify the measurements, in most of the MS analyses, proteins are enzymatically digested (either individually purified or in mixtures) to produce peptide fragments. The resulted peptide mixtures are often fractionated further. Fractionation of the peptide mixtures is usually achieved via in-liquid chromatography methods.

Isolation of a particular subcellular compartment or an organelle is usually achieved by a combination of centrifugation and solubilization steps. Proteins modified posttranslationally in a specific way (e.g. phosphoproteins) can be isolated by chemical- or immunoaffinity methods (see examples in Sect. 3). Large-scale isolation of protein complexes can be done by the epitope tagging and subsequent immunoaffinity purification (see examples in Sect. 3). Another promising affinity

method is that of protein chips – a method that uses large arrays of antibodies, or other binding factors to isolate proteins of interests.

1.5.1 2D-electrophoretic Separation of Complex Protein Mixtures

2D PAGE separation methods were introduced in mid-1970s and were extensively used for analysis of complex protein mixtures. The principle of 2D PAGE separation is illustrated in Fig. 4. 2D PAGE separates proteins in the first dimension by their pI, and in the second, by their molecular weight. Prior to the development of MS-identification techniques suitable for macromolecules, identification of individual proteins in the gel spots was difficult. Typically, the identification of individual proteins in the gel spots was done by immunostaining methods or by N-terminal degradation sequencing. Nowadays, in most laboratories, analysis of 2D PAGE spots is performed with MS. Typically, the individual spots are excised, digested, and analyzed by MALDI-MS. Protein identification is achieved by peptide mapping – comparison of the observed peptide peak patterns with the predicted digest fragments of proteins in a database. However, if some of the spots on the 2D PAGE are overlapping, the method of peptide mapping can give incorrect results.

As a separation technique, 2D PAGE offers high resolution, and is able to distinguish between different protein isoforms and also between different posttranslational modification

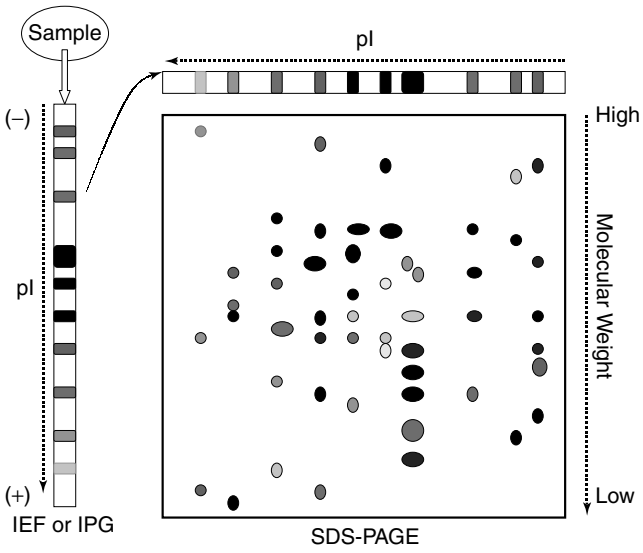

Fig. 4 Principle of the two-dimensional electrophoretic separation of intact proteins. The sample is loaded onto IEF to IPG strip, where proteins are separated according to their isoelectric points (pI). Next, the strip is loaded on SDS-PAGE, where the proteins are separated according to their molecular weights (MW). Visualization of protein spots is achieved via chemical staining methods. Individual spots can be further excised and analyzed by mass spectrometry.

states. However, 2D PAGE is a denaturing technique; hence, it is not suitable for direct analysis of protein complexes and protein–protein interactions. Also, 2D PAGE is known to discriminate against low-abundance and membrane proteins. Other limitations of 2D PAGE include biases against proteins with pIs outside the 2–10 range and biases against heavy proteins (>100 kDa). The dynamic range of 2D PAGE is also limited by resolution of the spot visualization methods. Recently, a number of ways to overcome some of these limitations of 2D PAGE have been developed.

Significant improvement to 2D PAGE was the development of immobilized pH gradients (IPGs), which increased both reproducibility and the load capacity of 2D PAGE. Sample prefractionation into discrete isoelectrical fractions and subsequent analysis by several narrow-range IPGs is yet a further improvement to this technology, which both increases the method's dynamic range and somewhat reduces the biases in proteome coverage. Despite these technological improvements, 2D PAGE remains a time-consuming and labor-intensive technique. Alternative methods of protein separations employing LC exist and can potentially overcome some of the 2D PAGE's limitations in the large-scale proteome analysis.

1.5.2 **Liquid-phase Separation Methods**

An ESI source allows MS characterization of proteins and peptides that are present in solutions and therefore is ideally suited for online coupling with liquid-phase separations. Liquid-phase separation can be achieved by using high performance liquid chromatography (HPLC), capillary isoelectric focusing (CIEF), capillary electrophoresis (CE), or by other methods. When two or more distinct liquid phases are used in a separation, with each of the phases relying on a unique independent physical property of the analyte, this liquid-phase separation is called *multi-dimensional*. Independent physical properties correspond to ''dimensions'' and these can be size, charge, hydrophobicity, or affinity to a particular substrate. The use of several independent dimensions significantly increases resolving power of a separation.

In-liquid separation methods can be used both for the intact proteins and for the peptide mixtures. One promising technique for characterization of global extracts of intact proteins is CIEF-FTICR mass spectrometry. In this method, the CIEF separates intact proteins by pI and subsequent analysis by FTCIR produces a two-dimensional display similar to the one obtained in 2D PAGE. Jensen et al. reported resolution of 400 to 1000 proteins in the mass range of 2–100 kDa from global protein extracts of *Escherichia coli* and *Deinococcus radiodurans*. While of good resolving power and sensitivity, this technique needs further improvement, perhaps by addition of protein fragmentation so that the resolved proteins could be identified.

Wall et al. developed a method that can potentially obtain both intact protein molecular weights as well as sequence information for a large portion of a proteome. In this method, proteins were separated by pI using isoelectric focusing (IEF) in the first dimension and by hydrophobicity using nonporous reversed-phase HPLC in the second dimension (IEF-NP RP HPLC). Next, the fractions that were eluted from HPLC were analyzed in two parallel experiments by (1) MALDI-TOF-MS and (2) ESI-TOF-MS. Analysis of human erythroleukemia cell lysate by this method resulted in resolution and identification of

several hundreds of unique proteins in a mass range from 5 to 85 kDa. Having both intact protein molecular weights as well as sequence information alleviates characterization of protein posttranslational modifications and isoforms. Thus, Wall et al. reported detection of posttranslational modifications of cytosolic actin, heat shock 90 beta, HINT and α-enolase.

The intact protein approaches are usually limited to proteins of smaller sizes, mostly because the resolving power of mass analyzers drops with increase in the ions masses. Also, biases toward one or the other types of intact proteins are unavoidable with any chromatographic separation method. A conceptually different approach, in which purification of intact proteins is avoided, involves proteolytic digestion of protein mixtures. Proteolytic digestion transforms protein mixtures into more uniform (in terms of mass and chromatographic properties) mixtures of peptides. Because of the increased uniformity, analysis of peptide mixtures essentially eliminates biases in proteome coverage. Unfortunately, the absence of information on intact proteins makes characterization of posttranslational modifications more difficult.

Chemical or enzymatic cleavage of proteins into peptides followed by multidimensional liquid-phase separation is typically used in a global proteome survey type of experiments. Generally, proteins from whole cells or tissue homogenates are first enzymatically digested and then the resulting peptide mixtures are separated by electrophoresis or liquid chromatography in a microcapillary format. A microcapillary column is attached directly to the ionization source so that the eluting fractions are ionized and introduced to a mass analyzer. While fragmentation of the peptide ions is optional with MALDI-MS/peptide mapping analysis of 2D PAGE spots, it is required with the liquid-phase/MS analysis of complex peptide mixtures. The sequence information obtained by MS/MS for individual peptide ions is used to match peptides to the corresponding proteins in a database.

Multidimensional protein identification technology (MudPIT) is a good example of a liquid-phase/MS method. In MudPIT, a biphasic SCX/RP microcapillary column is used to fractionate a complex peptide mixture (Fig. 5). The peptide fractions are eluted from the column by series of HPLC gradients into the tandem mass spectrometer. The obtained MS/MS spectra are used to search a sequence database via SEQUEST algorithm. MudPIT was used to detect and identify ~1500 proteins from *Saccaromyces cerevisiae* proteome, ~2500 proteins from the *Oryza sativa* proteome and ~2500 proteins from the *Plasmodium falciparum* proteome.

1.5.3 Affinity Methods (Epitope Tagging)

Affinity-purification methods are frequently employed in those proteomics programs that analyze specific subsets of a proteome, such as phosphorylated or glycosylated proteins. Also, affinity methods are often used in large-scale studies of protein–protein interactions and protein complexes. Affinity methods are based on targeted interactions between proteins and antibodies or between proteins and other protein-specific molecules, immobilized in a column or in the form of an array. For example, to isolate phosphorylated proteins from the rest of the proteome, one can use an immunoaffinity column prepared with antibodies specific to the phosphorylated amino acids.

Epitope tagging is used in large-scale analyses of protein–protein interactions and protein complexes (Fig. 6). In this

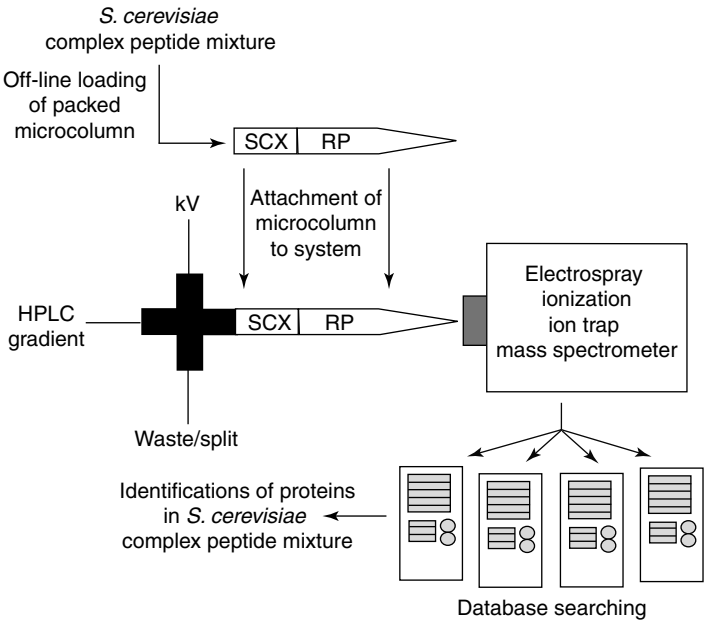

Fig. 5 Multidimensional protein identification technology (MudPIT). Complex peptide mixtures are loaded onto a biphasic microcapillary column packed with strong cation exchange (SCX) and reverse-phase (RP) materials. Peptides directly elute into the tandem mass spectrometer because a voltage (kV) supply is directly interfaced with the microcapillary column. Peptides are first displaced from the SCX to the RP by a salt gradient and are eluted off the RP into the MS/MS. The tandem mass spectra generated are correlated to theoretical mass spectra generated from protein or DNA databases by the SEQUEST algorithm. Figure is reproduced from Washburn, M.P., Wolters, D., Yates, J.R. III (2001) Large-scale analysis of the yeast proteome by multidimensional protein identification technology, *Nat. Biotechnol.* **19**, 242–247 by permission of Nature Publishing Group.

strategy, proteins to be isolated are fused with a motif recognizable by a specific antibody. This fusion is typically done by incorporating the epitope sequence into C-terminal of genes that encode proteins of interest. Then the fused proteins are expressed and purified along with their interaction partners by the immunoaffinity chromatography using antibodies specific to this particular epitope. If a particular protein is of low abundance, it can be overexpressed to increase the overall recovery.

1.6 Protein Identification by MS

Accurate identification of proteins is the essential requirement of proteomics studies. High complexity of protein mixtures derived from tissues, whole cells, or subcellular compartments adds an additional requirement of high throughput in the identification of proteins. In this section, we review common strategies that match MS data with proteins present in a biological sample.

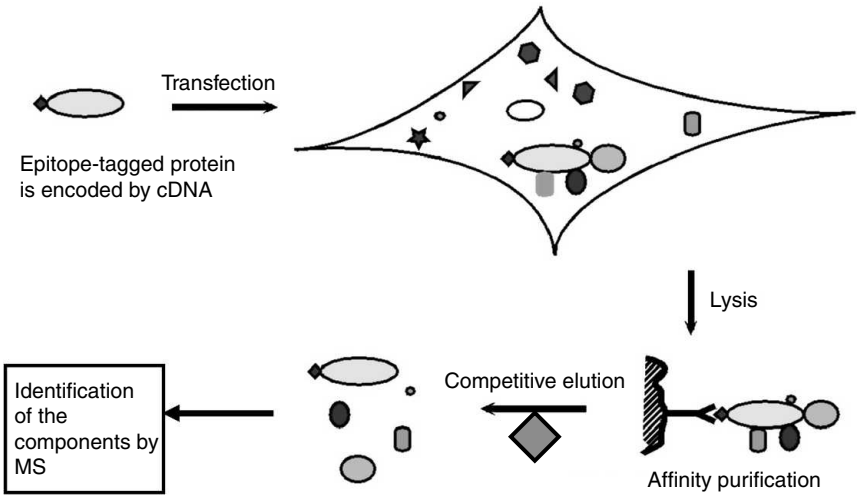

Fig. 6 Principle of affinity purification with epitope tagging. Bait proteins are expressed as fusion with a motif recognizable by a certain antibody (epitope). The cells are lysed, and proteins are purified by immunoaffinity chromatography. Next, the bound fraction is competitively eluted from the column, and the pulled proteins are analyzed by LC/MS or 1D PAGE/MS.

Typically, protein identification amounts to the deduction of the sequence-specific information from MS data followed by searches of the sequence databases. Databases that MS data can be matched against are protein, expressed sequence tag (EST), and genomic databases. Because currently there are no suitable ways to fragment intact proteins inside a mass spectrometer, high-throughput sequencing by MS is possible only if intact proteins are fragmented into peptides first. Depending on a particular type of proteomics scheme and MS instrumentation used, protein sequence information can be obtained by (1) peptide mass fingerprinting; (2) accurate mass tags (AMTs); (3) peptide fragmentation in MS/MS; (4) sequence tags; or by combinations of (1) through (4).

Peptide mass fingerprinting method is usually adopted in those cases in which individual proteins are separated during purification steps, such as in 2D PAGE. In the case of 2D PAGE, individual spots are picked, digested, and masses of the peptides are recorded. Next, the experimentally obtained peptide masses are matched against theoretical peptide libraries generated from protein sequence databases. MS/MS data can also be obtained along with mass fingerprinting, and nowadays this is a common practice.

With MALDI-TOF instrumentation – which is typically used with the peptide mass fingerprinting type of analysis – several peptide masses are needed to unambiguously identify a protein. Using more accurate instrumentation, such as FTICR-MS, it is possible to identify proteins based on the mass of a single peptide, without MS/MS data. In this case, a peptide that uniquely corresponds to a protein is called *accurate mass tag* (AMT). Conrads et al. evaluated utility of AMTs for identification of proteins from *S. cerevisiae* and *Caenorhabditis elegans*. The

authors demonstrated that up to 85% of the predicted tryptic peptides from these two organisms could be used as AMTs at mass accuracies typical of FTICR-MS instruments (~1 ppm). The authors also discussed utility of AMTs with highly accurate mass measurements in detection of phosphorylated proteins. They argued that because mass defect of P is larger than that of H, C, and O, the average mass of phosphopeptides is slightly lower than the mass of unmodified peptides of the same nominal weight; thus enabling the identification of phosphorylated peptides if the mass measurement accuracy is sufficient.

Whenever it is possible to match a single peptide to a protein, it is no longer necessary to purify samples down to individual proteins. Instead, fractions containing mixtures of proteins can be digested with trypsin followed by analysis of the resulted peptide fragments. For example, the above-discussed AMT method can be used for analysis of complex protein mixtures, because it matches single peptide to a unique protein. However, the requirement of high mass accuracy makes uses of AMT limited. Additionally, FTICR instrumentation is cumbersome and is not a widely distributed technology today. Far more superior in terms of proteome coverage per monetary cost are methods that employ peptide sequence analysis by MS/MS. The key fact that enables high-throughput peptide sequencing by MS/MS is predictability of the peptide precursor ion fragmentation in the CID reactions.

Figure 7 shows the adopted nomenclature for the fragment ions series. Ions that form through dissociation of the peptide bonds are the most abundant ones if moderate collision energies are used (30–50 V). The ions that retain their charge on the N-terminal part after fragmentation of the precursor are called *y* ions, and the

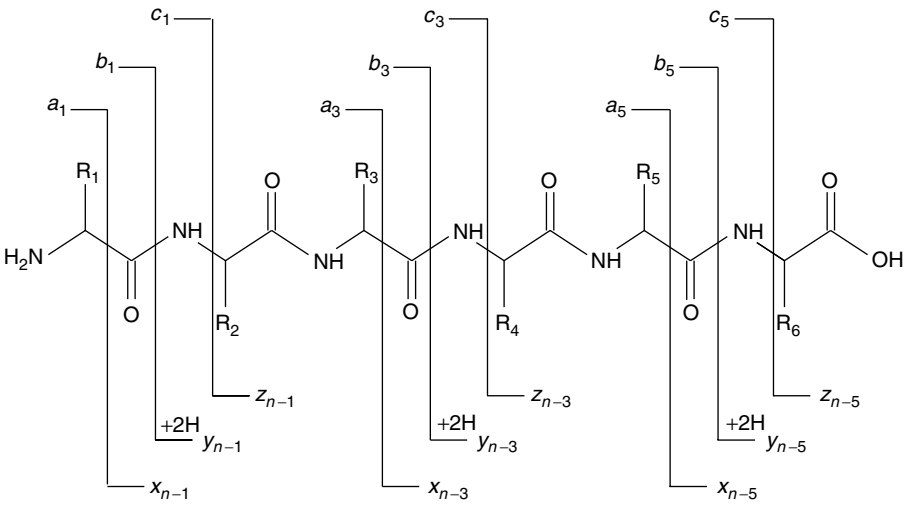

Fig. 7 Nomenclature of the ions formed during peptide fragmentation. In a typical MS/MS experiment via CID reactions, *y* and *b* ions are predominant. These two types are used for computer-assisted peptide identification. Through the loss of CO fragment, *a* ions can be produced from *b* ions. While not important for identification, *a* ion series can be used for independent result validation. Other types of ions are not produced in CID reactions.

ions that retain their charge on the C-terminal part after fragmentation of the precursor are called *b* ions. The subscript to the right of *b* and *y* symbols equals the number of amino acid residues in the corresponding fragment. The difference in m/z values between consecutive ions within a given series corresponds to the difference in the sequences of the two fragments. Because the consecutive ions within a series represent peptide fragments that differ in exactly one amino acid, and each amino acid residue has a unique nominal weight (except I and L), the pattern of m/z values of *y* and *b* ions corresponds to the amino acid sequence of the precursor peptide. Unfortunately, some expected peaks could be missing from the MS/MS. Additionally, experimental spectra can be complicated by unwanted fragmentation. Also, it is not always possible to unambiguously determine from which series a particular ion fragment comes. For these reasons, manual interpretation of MS/MS spectra can be tedious and ineffective. As a consequence, *de novo* sequencing is rarely done in high-throughput proteomics experiments. Instead of direct interpretation of the MS/MS spectra, computer programs that find the best matches to the spectra from a database are used.

Typical example of an algorithm that finds best matches to MS spectra is SEQUEST software package developed by Eng et al. Analysis of MS data by SEQUEST starts with reduction of tandem spectra complexity. Only a certain number of most abundant ions are considered and the rest are discarded. Also, the unfragmented precursor ion is removed from the spectra in order to prevent its misidentification as a fragment. Next, SEQUEST selects sequences from a database. First, SEQUEST creates list of peptides that have masses at or near the mass of the precursor ion. Second, SEQUEST generates virtual MS/MS spectrum for each of the candidate and compares them to the observed spectrum. As the result of this comparison, a cross correlation score is produced (Xcorr). Another score, DeltaCN, reflects the difference in correlation of the second ranked match from the first one. The higher this score is, the more likely it is that the first match is the correct one.

SEQUEST also has the ability to detect posttranslational modifications. In this case, SEQUEST looks for increased masses of amino acids. For example, cysteines are typically carboxymethylated by iodoacetomide prior to enzymatic digestion. In this case, masses of all cysteine residues are considered to increase by 57 Da. To look for amino acids that can be either modified or not modified, the database size is increased by allowing different weights to represent the same amino acid. Unfortunately, only known posttranslational modification can be detected by SEQUEST – the types of modifications that are being looked at need to be explicitly specified in input parameters.

Another useful technique for peptide identification is sequence tag. This technique is implemented in algorithms such as GutenTag. In GutenTag, a partial sequence is inferred directly from the tandem spectrum, and then the database is searched for matches that include this partial sequence and that match the masses on C- and N-sides of the fragment. Importantly, GutenTag method is error-tolerant, and allows detection of unknown posttranslational modifications. A recent variation of this method, MultiTag also allows protein identification from organisms with unsequenced genomes.

2 Quantitative Methods of Proteome Analysis Using MS

Quantitative proteome analysis aims at large-scale identification of differences in protein expression. Two-dimensional difference gel electrophoresis (2D-DIGE) is one of the techniques that can achieve that aim. Recent example of application of this technique is the report by Friedman et al. The authors used 2D-DIGE in combination with MALDI-TOF to analyze the proteome of human colon cancer. However, while acknowledging the importance of the gel-based methods in modern quantitative proteomics, we believe that methods based on multidimensional chromatography have greater potential, and therefore, we limit our further discussion to quantitation within the LC/LC/MS/MS paradigm.

Even though absolute quantification (i.e. clear relationship between the peak intensity and amount of the analyte) is a challenge for modern mass spectrometers, methods of finding relative abundances exist. These methods are based on labeling through mass modifications of the whole proteome or some of its subsets. Labeling through mass modification is particularly suited for quantitative analysis in differential expression profiling, where two states under study are differentially labeled via ''light'' or ''heavy'' mass modifications. Figure 8 schematically depicts a quantitative proteomics approach. Mass modification can be introduced at different steps in the sample preparation – during growth, after growth, during digestion, or after digestion. Labeling at the early stages of sample preparation minimizes losses of the analytes. Instrumentation for quantitative studies is essentially the same as instrumentation for qualitative studies. Nevertheless, quantitative analysis is more laborious and typically achieves lower proteome coverage. Also, quantitative methods in proteomics are still at the stage of development and are not as broadly applied as qualitative methods.

2.1 Metabolic Labeling

Widely used in structural biology to prepare samples for analysis by nuclear magnetic resonance (NMR) analysis, metabolic labeling methods have become useful quantitative proteomics tools. Metabolic labeling is a mass modification method that is done very early in the experiment – at the stage of cell growth. Figure 8 illustrates the principle behind this strategy. The goal is to compare protein abundances in cells grown at different conditions. To do this, the growth media from one of the conditions is enriched in stable low-abundant isotopes. The enrichment can be done either by labeling all amino acids by ^{15}N, or by supplementation with a single labeled amino acid. The processed and digested cell extracts from the two different conditions are combined in a one-to-one ratio and analyzed by liquid-phase/MS/MS methods. In the resultant MS spectra, peaks corresponding to the same peptide from different conditions are offset according to the degree of labeling. The ratio between the two peaks corresponds to the difference in abundances.

The first demonstrations of metabolic labeling in quantitative proteomics used gel electrophoresis and spot excision as the protein isolation method. For example, Oda et al. identified proteins that were altered in expression between two strains of *S. cerevisiae* grown in ^{14}N or ^{15}N media, and determined the phosphorylation levels of a specific protein in the same

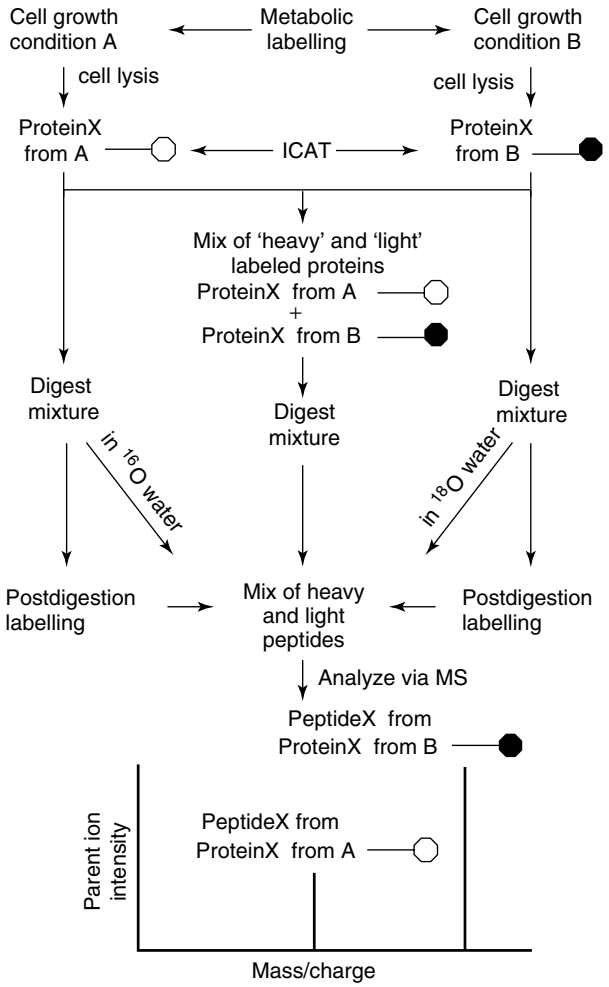

Fig. 8 Quantitative proteomics approach. When carrying out a quantitative proteomic analysis, the key is for the same peptide from two unique growth conditions to have unique masses when being analyzed by a mass spectrometer. ''Heavy'' and ''light'' peptides may be generated at many points in a sample preparation pathway. Metabolic labeling introduces a label during the growth of the organism and is therefore the earliest point of introduction of ''heavy'' and ''light'' labels. Metabolic labeling is followed by ICAT, digestion in ^{16}O and ^{18}O water, and lastly postdigestion labeling. Only after a label has been introduced can the samples be mixed and further processed. Figure and figure legend are reproduced from Washburn, M.P., Ulaszek, R., Deciu, C., Schieltz, D.M., Yates, J.R. III (2002) Analysis of quantitative proteomic data generated via multidimensional protein identification technology, *Anal. Chem.* **74**, 1650–1657 by permission of Analytical Chemistry.

sample. Complete metabolic labeling has been demonstrated using chromatography based proteomics methods on *D. radiodurans*, mouse B16 cells, and on *S. cerevisiae*.

In addition, isotopically enriched single amino acids may be used for the selective metabolic labeling of a cell type for a quantitative proteomic analysis. In *S. cerevisiae*, Jiang et al. have described the single amino acid isotopic enrichment of *S. cerevisiae* with D_{10}-Leu, and Berger et al. described the comparative analysis of *S. cerevisiae* cultured in media containing either ^{13}C-Lys or unlabeled lysine. Stable isotope labeling by amino acids in cell culture (SILAC) was explored as an alternative to ^{15}N labeling. Ong et al. studied mammalian cells grown either with deuterated or nondeuterated leucine. Importantly, parameters such as cell morphology, doubling time, and ability to differentiate did not change in deuterated sample compared to nondeuterated one. The authors used this technique to study changes in protein expression induced by muscle cell differentiation. The authors reported that glyceraldehyde-3-phosphate dehydrogenase, fibronectin, and pyruvate kinase M2 were upregulated. Another approach to metabolic labeling is the rare isotope depletion of the growth media from one of the conditions under study. If the rare isotopes are removed, then one expects m/z distributions to shift to the lighter values. With conventional instrumentation, this could work for large proteins. However, high-resolution instrumentation like FTCIR must be used to analyze peptide mixtures.

2.2 Isotope Coded Affinity Tags

Metabolic labeling with stable isotopes while analytically advantageous to other methods is available only in cases when studied cells or organisms are cultivable. For this reason, metabolic labeling is not suitable for diagnostic and clinical applications. When cultivation or controlling growth is difficult, different strategies need to be used for quantitative proteome analysis. One of the possible approaches is the method that uses cysteine-specific reagents – isotope coded affinity tags (ICATs) – to differentially label proteomics samples. ICATs have three functional elements: cysteine-specific reactive group, isotopically labeled linker, and affinity group (Fig. 9). For the comparative analysis, the cysteine residues in samples are separately labeled with either labeled or unlabeled ICAT. The derivatized samples are then combined in a one-to-one ratio and digested with a protease resulting in both labeled and unlabeled peptide fragments. The labeled peptide fragments are then purified by affinity chromatography, fractionated by reversed-phase chromatography and analyzed by tandem mass spectrometry, which provides both qualitative analysis and the relative abundance of the peptide isoforms in the samples. The MS analysis is analogous to metabolic labeling case – ratio of ''heavy'' to ''light'' peptide ions correlates with their relative abundance. Also, the ICAT approach has the obvious conceptual limitation – only peptides that contain cysteine can be detected. It has been shown that in yeast only ~10% of all tryptic peptides contain cysteine. Therefore, full sequence coverage may not be possible even for the most abundant proteins.

Significant improvement to the ICAT method is the cleavable ICAT (cICAT), which is presently supplied by Applied Biosystems in a kit format. The cICAT reagent has four essential structural elements. The first is a protein reactive group

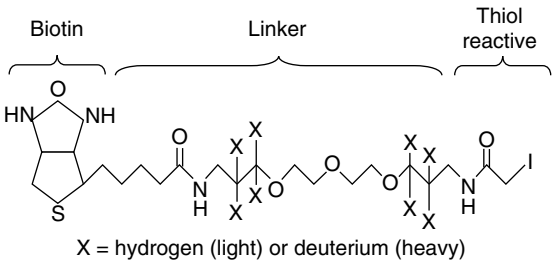

Fig. 9 Structure of isotope coded affinity tags. The ICAT reagent consists of a biotin group linked to a cysteine reactive group. The linker may be deuterated eight times or protonated at each site allowing for the generation of D_0- or D_8-ICAT. The differential masses of the linker group allow for the use of ICAT in a quantitative proteomic scheme. The figure and figure legend have been reproduced from Hunter, T.C., Washburn, M.P. (2003) The integration of chromatography and peptide mass modification for quantitative proteomics, *J. Liq Chromat. Rel. Technol.* **26**, 2285–2301 by permission of Marcel Dekker, Inc.

(iodoacetamide) that covalently links the isotope-coded affinity tag to the protein through alkylation of cysteines. The second structural element is the biotin affinity tag that allows enrichment of the tagged peptides. The third is an isotopically labeled linker ($C_{10}H_{17}N_3O_3$). Nine carbon atoms of the linker can be either ^{12}C or ^{13}C giving light and heavy version of the tag respectively. The light and heavy molecules have the same chromatographic properties, but differ in mass (9 Da). Once the sample is subjected to mass spectrometric analysis, the ratio of intensities between heavy and light peptides provides a relative quantitation of the proteins in the original sample. The fourth structural element of cICAT is an acid cleavage site that allows removal of part of the tag prior to MS analysis. After avidin-affinity purification of the cICAT-labeled peptides, biotin portion of the label and part of the linker can be removed by adding trifluoroacetic acid. This reduces the overall mass of the tag on the peptides and improves the overall peptide fragmentation efficiency.

The ICAT methodology has been successfully applied to a variety of biological questions including studies of several cell types, organelles, and different classes of proteins. Quantitative proteomic analysis via ICAT has been coupled with cDNA array analysis to investigate the galactose utilization pathway in *S. cerevisiae* and to investigate the mRNA and protein expression changes brought about by culturing *S. cerevisiae* in either galactose or ethanol. In addition, ICAT detected changes in protein expression of peripheral and integral membrane proteins by analyzing the effect on 12-phorbol 13-myristate acetate on the microsomes of HL-60 cells. Of all non-gel-based quantitative proteomic strategies, ICAT is the most mature as demonstrated by the successful use of ICAT in biologically driven analyses.

2.3 ^{18}O Labeling

The global modification of all proteolytic peptides in a mixture may be carried out via the labeling of carboxyl groups that occurs through incorporation of ^{18}O from $H^{18}O$ during proteolytic hydrolysis (Fig. 10). In order to introduce a 4-Da mass shift into the C-terminus of a peptide, proteins may be digested in the presence of $H_2{}^{18}O$. Proteases like trypsin will carry out this

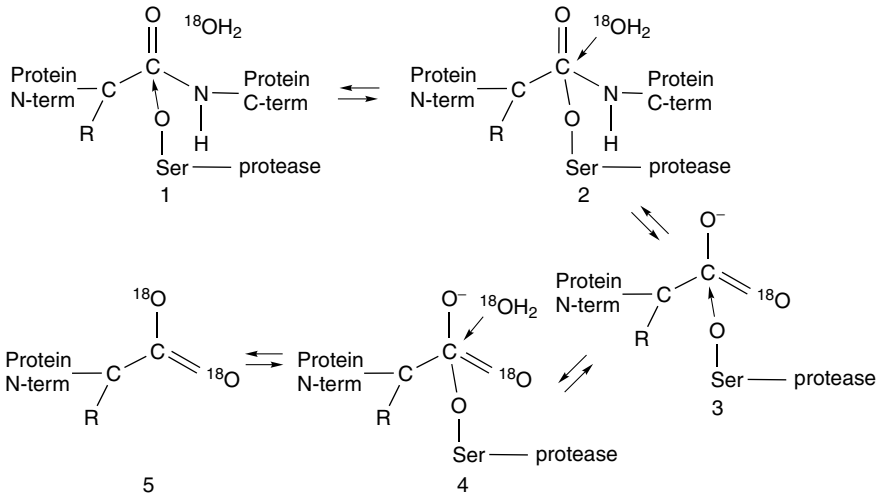

Fig. 10 C-terminal digestion modification with ^{18}O. ^{18}O may be incorporated into the C-terminus of a peptide during digestion with enzymes such as trypsin, endoproteinase Lys-C, and endoproteinase Glu-C. A simplified version of this reaction scheme is shown. (1) To begin, the peptide needs to be digested in $^{18}OH_2$ in order to then incorporate ^{18}O. The serine in the active site of the proteases listed attacks the carbonyl carbon in a peptide bond. (2) Next, $^{18}OH_2$ attacks the protein–protease intermediate also at the carbonyl carbon displacing the NH group on the peptide bond. (3) As a result, a peptide with a single ^{18}O has been generated. (4) A repeat of steps (1) and (2) is needed to drive the reaction to completion as shown in (5) where two atoms of ^{18}O have now been incorporated into the peptide C-terminus. Labeling of one sample with ^{18}O by digesting in $^{18}OH_2$ and mixing this with the other sample digested in ^{18}O depleted water allows for the determination of the relative abundance of peptides from a mixture. Figure and figure legend is reproduced from Hunter and Washburn (2003) by permission of Marcel Dekker, Inc.

reaction during the process of enzymatic cleavage. By mixing a sample with proteins digested in the presence of ^{18}O and the absence of ^{18}O, a pairwise comparison may be made to determine the relative abundance of peptides in a sample.

2.4 Postdigestion Labeling

There are several alternatives to the residue-specific modification of cysteine, which include methods for differential modification of lysine and O-phosphorylated serine residues. The phosphoprotein isotope coded affinity tag (PhIAT) method has been shown to be capable of enriching and identifying mixtures of low-abundance phosphopeptides. The PhIAT method uses a chemical modification of phosphorylated serine and threonine residues to cysteine before introduction of a standard ICAT reagent. The mass-coded abundance tag (MCAT) approach uses a residue-specific modification lysine residues by *O*-methylisourea to introduce a differential tag. In addition, 2-methoxy-4,5-dihydro-1H-imidizole has also been used to modify lysine residues for the purpose of introducing a differential mass tag.

The N/C termini of peptides after digestion may also be labeled through a variety of means. A C-terminal modification

method is methyl esterification of carboxyl groups using either methanolic HCl or the deuterated analog. In this case, multiple sites in a peptide may be modified with labels introduced at aspartic acids, glutamic acids, and C-termini. The N-terminal labeling of tryptic peptides with *N*-hydroxysuccinimide or 1-Nicotinoyloxysuccinimide esters and their stable isotope analogs is another approach that can be potentially used for quantitative proteomic analyses. In fact, coupling ^{18}O labeling and N-terminal labeling methods for protein expression profiling produced more comprehensive results than when either method was used alone.

2.5 Global mRNA and Protein Expression Analyses

An emerging application of quantitative proteomics approaches includes the large-scale analysis of protein expression correlated to large-scale mRNA expression analyses. In three independent comparisons of mRNA and protein levels in *Saccharomyces cerevisiae*, overall partial positive Spearman rank correlation coefficients ranging between 0.21, 0.45, and 0.57 were obtained. These studies employed ICAT, chromatography, and mass spectrometry, ^{15}N labeling and MudPIT or chemiluminescence of SDS-PAGE approaches to determine protein expression levels in cells grown under different conditions in each study. In all likelihood, this pattern of partial positive correlation between mRNA and protein expression levels could be expected to persist under a variety of conditions in *S. cerevisiae*. When these approaches begin to be globally applied to other organisms, it will be interesting to see if this trend persists.

3 Specific Examples of Applications

3.1 Global Proteome Sampling

The goal of global proteome sampling is the simultaneous identification of proteins in a cell or tissue at a given condition. Data obtained in such experiments can be further used to answer more specific biological questions, such as difference between healthy and pathological states. Typically, the proteins are identified by mass spectrometry and are grouped into functional categories.

3.1.1 Global Proteome Sampling Based on 2D Page

Global proteome analysis by 2D PAGE method is difficult because each spot needs to be picked and identified individually, thus increasing time and cost of the analysis. Also, as we discussed earlier, 2D PAGE separation suffers from biases – certain classes of proteins, such as hydrophobic or those of high molecular weight are difficult to detect. Apart from these limitations, 2D PAGE approach has an important advantage over other methods – it easily resolves protein isoforms.

In their analysis of *Haemophilus influenzae* proteome, Langen et al. used several techniques to maximize the 2D PAGE performance. To increase the proteome coverage, they used immobilized pH gradient strips covering several pH regions. Also, to visualize low-copy-number proteins, the authors performed a series of protein extractions, such as heparin chromatography, chromatofocusing, and hydrophobic interaction chromatography. In order to detect cell-envelope-bound proteins, the authors used immobilized pH gradient strips in

combination with a two-detergent system with a cationic detergent in the first and an anionic detergent in the second dimensions. The isolated proteins were identified by MALDI/MS and peptide fingerprinting. As a result, 502 unique proteins were identified (about 30% of all ORFs)

Analysis of the mouse brain proteome performed by Klose et al. provides a good illustration of what 2D PAGE can do for the global proteome sampling type of experiments. By using 2D PAGE, the authors performed comparative analysis of the two distantly related mouse strains, *Mus musculus* C57Bl/6 (B6) and *Mus spretus* (SPR). About 8700 proteins from the cytosolic fraction of brain proteome were compared between the two species. By analyzing 2D PAGE of B6 and SPR strains, as well as of F_1 (B6 × SPR) and B_1 (F_1 × SPR) hybrids, the authors detected 1324 species-specific polymorphisms. Among these, 466 proteins were identified by MALDI-TOF/MS using peptide mass fingerprinting. To detect the polymorphisms, the authors considered variations in electrophoretic mobility, spot intensity, and the number of different isoforms corresponding to one protein. Additionally, through the analysis of F_1 and B_1 generations, the authors established which polymorphisms were genetically dominant. The key feature that enabled this comprehensive study was the high quality of the 2D PAGE. To analyze the mouse brain proteome, the authors used the large-gel 2D PAGE, which employs IEF gel incubation, and large (46 × 30 cm) format. Implemented in this way, the 2D PAGE gives both high resolution and high sensitivity – more than 10 000 protein spots from mouse tissues can be visualized simultaneously.

3.1.2 Global Proteome Sampling Based on Multidimensional LC

When it is necessary to catalog proteins present in a cell or an organism in a given environmental context, the multidimensional LC separation of peptide mixtures followed by MS/MS is the most convenient method to use. While it is not as good at determining protein isoforms and posttranslational modifications as 2D PAGE, the biases in proteome coverage are greatly reduced.

Florens et al. performed proteomics studies of the life cycle of the human pathogen *Plasmodium falciparum* (malaria) life cycle. The authors identified 2415 proteins and assigned them to functional groups at four stages of the cycles (sporozoites, merozoites, trophozoites, and gametocytes). The sporozoite is the form in which *P. falciparum* is injected by a mosquito. The merozoite is the form that invades erythrocytes. The trophozoite is the form that multiplies in the erythrocytes. The gametocyte is the sexual stage of malaria parasite life cycle. The analysis was performed by MudPIT. The authors found that about 50% of sporozoite proteins were unique to that stage. In sporozoites, about 25% were shared with any other stage. Trophozoites, merozoites, and gametocytes had 20 to 30% unique proteins and they had 40 to 60% of their proteins shared. Only 6% of all identified proteins were shared between all four stages, which were mainly histones, ribosomal proteins, and transcription factors. Out of the 2415 identified proteins, 51% were previously annotated as hypothetical.

Koller et al. used both 2D PAGE and MudPIT to analyze *Oryza sativa* (rice) proteome. The analyses were performed on the protein extracts from leaf, root, and seed tissue. The goal of this study was to determine tissue-specific expression of

proteins. 2D PAGE separation followed by MS/MS yielded 556 unique protein identifications, comprising 348 proteins from leaf, 199 from root, and 152 from seed. MudPIT analysis resulted in significantly larger coverage: 2363 total proteins, with 867 from leaf, 1292 from root, and 822 from seed. A total of 165 proteins were uniquely detected by 2D PAGE, whereas 1972 proteins were uniquely detected by MudPIT. Next, the authors searched the nonredundant protein database by BLAST and grouped the identified proteins into functional categories. The largest category (32.8%) included proteins that had no homology to the predicted proteins. Proteins classified as involved in metabolism comprised 20.8% of all identified proteins. Out of the 2528 detected proteins, 189 were shared among all three tissues. These included housekeeping proteins that are involved in transcription, mRNA biosynthesis, translation, and protein degradation. However, most of the proteins had tissue-specific expression: 622 specific to leaf, 862 specific to root, and 512 specific to seeds.

To characterize the proteome of *S. cerevisiae* mitochondria, Sickmann et al. combined four separation methods: IEF-incubated 2D PAGE; digestion with four different proteases, followed by multidimensional LC/MS/MS; SDS/PAGE combined with multidimensional LC/MS/MS; treatment of mitochondria with trypsin, followed by SDS/PAGE or HPLC and MS/MS. The authors identified a total of 750 mitochondrial proteins. When classified into functional categories, 24.9% of all the identified proteins were of unknown function, 24.9% were involved in genome maintenance and gene expression, and 14.1% were involved in energy metabolism. The rest of the identified proteins were involved in metabolism, transport, and cell rescue.

3.1.3 MS-assisted Disease Diagnosis from Serum Samples

Proteomics technologies recently emerged as a useful tool in clinical disease diagnosis. For example, Petricoin et al. used surface-enhanced laser desorption ionization time-of-flight (SELDI-TOF) and artificial-intelligence-based informatics algorithms to discriminate between control group and ovarian cancer patients. First, the authors generated a preliminary training set of mass spectra derived from 50 unaffected women and 50 women with ovarian cancer. Next, they used an iterative searching algorithm to find the best discriminatory pattern amongst these MS data. As a result, the algorithm correctly identified all cancer cases in the masked set. Additionally, out of 66 cases of malignant disease, only 3 were recognized as cancer (false-positives). Thus, the study by Petricoin et al. demonstrated good sensitivity and predictive power of MS-based proteomics when applied to clinical disease diagnosis. For further information on this subject, we refer the interested reader to the comprehensive review by Rosenblatt et al.

3.2 Analysis of Protein Modifications by Mass Spectrometry

In living organisms, protein activity is regulated mainly by covalent modifications, which occur either co- or post-translationally. Identification of types of modifications and their locations is often a necessary requirement for an understanding of the regulation and function of a given protein. There are hundreds of known protein modifications. Among

these, phosphorylation is, perhaps, the most important and widespread – about one-third of all proteins from mammalian genomes are thought to be phosphorylated. Another functionally important modification is glycosylation – glycosylated proteins are ubiquitous components of cellular surfaces where their oligosaccharide groups participate in a wide range of cell–cell recognition events. Comprehensive analysis of glycosylated proteins is more challenging than analysis of other modifications, mainly because the structure of oligosaccharide varies.

Other commonly occurring modifications that are involved in protein regulation and function are disulfide bonds, acetylations, and ubiquitinations. Some of these and other modifications are listed in Table 2. Changes in a protein length, either as a result of alternative splicing or protein truncations, also may be considered as protein modifications. Generally, it is difficult to identify protein truncations by methods that deal with protein/peptide mixtures, and often purification down to individual proteins is required in such cases (e.g. by 2D PAGE).

Currently available methods of large-scale analysis of modified proteins can be grouped into two major classes: those that use sample enrichment or chemical treatment prior to MS, and those that rely on MS data alone. Enrichment methods include affinity purification, chemical tagging followed by affinity purification, and immunoprecipitation. MS methods of detection and identification of modified peptides include neutral loss scan, precursor ion scan, postsource decay, and others.

Sometimes it is of special interest to obtain information on several types of modifications at once. If that is the case, computer programs such as GutenTag (see Sect. 2) can be used to analyze MS/MS data. Additionally, if mass changes introduced by modifications are known, the search for modified proteins can be done by SEQUEST with input parameters modified in accordance with the mass changes. However, generally, it is difficult to analyze modified peptides in the background of nonmodified peptides. Therefore, when it is clear what type of modification needs to be analyzed, the fractionation steps that enrich that particular modification need to be introduced into the experimental scheme.

Tab. 2 Common protein modification.

Modification	*Monoisotopic/average mass change*
Phosphorylation[a]	+79.9663/79.9799
Acetylation	+42.0106/42.0373
N-acetylglucosamine (GlcNAc)[a]	+203.0794/203.1950
Disulfide bond	−2.01565/2.0159
Methylation	+14.0157/14.0269
Hydroxylation	+15.9949/15.9994
Oxidation of methionine	+15.9949/15.9994
Ubiquitination of lysines	+114.0429/114.1040[b]

[a] Occurs on tyrosine, serine, threonine. Widespread throughout the proteome. Functions include protein regulation, signal transduction.
[b] Mass change is due to Gly–Gly residue, which is left on ubiquitinated lysines after trypsin digestion.

Below we discuss several illustrative examples of analysis of phosphorylated, glycosylated, and ubiquitinated proteins from recent literature. In addition, tools and techniques used in analysis of phosphorylation are generally applicable to analysis of many other modifications such as methylation and acetylation, while analysis of glycosylation poses additional analytical and instrumental challenges due to variability in structures of oligosaccharide groups. Ubiquitination, while not as frequent as phospho- and glyco modifications, is important for protein degradation in proteasomes.

3.2.1 Phosphorylated Proteins

Main tools in large-scale identification of phosphoproteins are enrichment by immobilized metal affinity chromatography (IMAC), chemical tagging, and immunoprecipitation by phosphor-specific antibodies. IMAC technology is based on methods developed by Andersson et al. and relies on interaction of phosphate group with immobilized Fe^{3+} ions. Ficarro et al. used IMAC combined with LC/MS/MS to characterize the phosphorylated portion of the yeast proteome. The authors showed that carboxylic acid interfered with IMAC purification, and needed to be protected. The protection was achieved by esterification with methanol in the presence of HCl. Phosphorylated tryptic peptides were identified via SEQUEST. From the whole cell lysate, Ficarro et al. detected more than 1000 phosphopeptides. From these, 383 sites of phosphorylation were determined. A potential improvement to this analysis would be the use of other proteinases in parallel with trypsin to increase the sequence coverage.

An enrichment technique that could also complement IMAC is immunoprecipitation with antibodies that bind to any protein that contain phosphorylated residues. While antibodies exist for phosphorylated serine, threonine, and tyrosine, only the anti-phosphotyrosine antibody binds strongly enough to allow enrichment. Pandey et al. used phosphotyrosine immunoprecipitation to study phosphorylation in HeLa cells in response to epidermal growth factor (EGF). The phosphopeptides were immunoprecipitated from untreated and EGF-treated cell lysates and resolved by electrophoresis. Individual gel bands were excised and studied by MALDI-MS and ESI-MS/MS. As a result, the authors identified Vav-2 as a substrate of EGF-receptor.

A report by Salomon et al. also gives a nice demonstration of analysis of phosphorylation in human cells. The authors used phosphotyrosine immunoprecipitation along with methyl esterification and IMAC combined with multidimensional LC/MS to assess tyrosine phosphorylation that occurs over time in myelogenous leukemia cells in response to treatment. The authors reported identification of 64 unique tyrosine phosphorylation sites in 32 proteins.

In another report by Ficarro et al., the authors used anti-phosphotyrosine immunoblots to study capacitation of human sperm. Capacitation is a cAMP-dependent process that is necessary for fertilization. The authors performed a comparative analysis of capacitated versus noncapacitated sperm. First, they separated sperm proteins by 2D PAGE followed by western blotting with anti-phosphotyrosine antibodies. In the next step, they excised and digested spots that exhibited phosphorylation, followed by IMAC to enrich for phosphopeptides with subsequent MS/MS analysis. As a result, the authors pinpointed several proteins that undergo phosphorylation upon capacitation

of the sperm. Additionally, the authors used differential isotopic labeling to quantify the phosphorylation. The labeling was achieved at the stage of protecting the carboxy groups prior to IMAC, by treatment of the peptide mixtures from capacitated and noncapacitated digests with CD_3OD/DCl and CH_3OH/HCl respectively. These two peptide mixtures were further combined in one-to-one ratio and analyzed by IMAC/LC/MS/MS. As a result of this quantitation, the authors found 20 unique peptides that exhibited different phosphorylation levels between capacitated and noncapacitated sperm.

Metabolic labeling strategy was first described to quantitate changes in phosphorylation. In this approach, cells from two batches that have potentially different levels of phosphorylated proteins are metabolically labeled with N^{14} and N^{15}. Next, the cells are lysed; the target proteins are purified, digested, and analyzed by MS. Changes in peak intensities that correspond to modified and unmodified peptides from the two conditions provide quantitation of phosphorylation.

Another way to quantitate phosphorylation levels is to use modified ICAT strategy. In this approach, the phosphate groups in phosphopeptides derived from two different conditions are chemically replaced with either labeled or unlabeled tags. The tagging involves the following steps: (1) beta-elimination of the phosphate groups; (2) addition of 1,2-ethanedithiol containing either four hydrogens (EDT-D_0) or four deuteriums (EDT-D_4); (3) biotinylation of the EDT group using (+)-biotinyl-iodoacetamidyl-3,6-dioxaoctanediamine. The tagged peptides are further affinity purified by avidin column and analyzed by LC/MS.

3.2.2 Glycosylated Proteins

The importance of protein glycosylation, especially during cell–cell communication in multicellular organisms, is often acknowledged by using the terms *glycobiology* and *glycomics*. Owing to a wide range of possible polysaccharide structures, analysis of glycosylation is not as straightforward as analysis of other posttranslational modification. Currently, there are no satisfactory methods for global, proteome-wide analysis of all glycoprotein forms. It is possible, however, to characterize glycoproteins with glycogroups of constant structure. It is also possible to globally map glycosylation sites.

As an example, consider a broad research question such as to identify and characterize glycosylated proteins in a given biological system. In such a case, hypothetical analysis could include the following steps: (1) proteolytic digestion; (2) enrichment for glycopeptides; (3) identification of glycopeptides by MS and MS/MS; (4) structure determination of polysaccharide groups by MS^n. Alternatively, one could also separate proteins by 2D PAGE, and use glycospecific staining methods to identify spots of interest. Also, during the MS part of analyses, it could be useful to separate constant glyco structures from the variable ones, as well as N-linked from O-linked ones. One of the problems in analysis of glycopeptides is that glycogroups are very labile. Because of this lability, peptide fragmentation in CID reactions is reduced, thus making sequencing by MS/MS more difficult. An alternative way is to chemically (e.g. with beta-elimination of O-linked oligosaccharides) or enzymatically (e.g. with *N*-glycosidase F) remove glycogroups prior to analysis and to use chemical tags.

In eukaryotes, the most widespread constant type of glycosylation is O-linked *N*-acetylglucosamine (*O*-GlcNAc), which is found on many nuclear and cytoplasmic proteins. Glycosylation of serine and threonine residues by *O*-GlcNAc is believed to compete with and complement phosphorylation in mediating protein–protein interactions. The proteins that are glycosylated by *O*-GlcNAc include RNA polymerase II, transcription factors, chromatin-associated proteins, nuclear pore proteins, protooncogenes, tumor suppressors, and proteins involved in translation.

Because *O*-GlcNAc and phospho groups modify essentially the same amino acids, it is of special interest to establish methods that can characterize these modifications simultaneously. In this pursuit, Wells et al. developed a method based on beta-elimination followed by Michael addition (BEMAD) of dithiothreitol (DTT) or biotine pentylamine (BAP). This method relies on the fact that *O*-GlcNAc groups are more prone to elimination than phosphate groups. With the right conditions of elimination, *O*-GlcNAc can be tagged selectively. The DTT and BAP tags also allow enrichment by affinity chromatography and are stable in MS/MS fragmentation, thus allowing identification of the modified sites. First, the authors tested their method on synthetic peptides, and then they performed analysis of several biological samples: Synapsin I from rat brain and nuclear pore complex (NPC). In Synapsin I, three novel *O*-GlcNAc sites, as well as three previously known sites were mapped, thus validating the method. In the nuclear pore complex, BEMAD also mapped novel *O*-GlcNAc sites in Lamin B receptor and Nup155. Using BEMAD along with modification-specific antibodies and enzymes, the authors were able to distinguish between *O*-GlcNAc- and phosphopeptides.

During CID reactions, oligosaccharide moieties fragment mainly at glycosidic bonds. This fact potentially allows discerning of a primary structure of an oligosaccharide in MS^n experiments. While technology for a large-scale structural analysis of glycoforms is not developed yet, oligosaccharide structure determination is certainly possible for individually isolated glycopeptides. Notable examples include characterization of lipooligosaccharides from *Haemophilus influenzae* and *Neisseria gonorrhoeae*.

3.2.3 Ubiquitinated Proteins

Degradation of proteins in living organisms is a complex, highly regulated process, which plays important roles in many cellular pathways. The first step in protein degradation is the attachment of ubiquitin moieties to lysines of the substrate. The second step is proteolysis of the tagged protein by proteasome. Given the importance of this posttranslational modification, it is surprising that the report by Peng et al. is perhaps the only paper in the literature that addresses large-scale analysis of protein ubiquitination.

Peng et al. described a systematic approach based on LC/LC/MS/MS to analyze protein ubiquitination in yeast. In this pursuit, Peng et al. expressed His-tagged ubiquitin in *S. cerevisiae cells* followed by purification over Ni-chelating resin. Denaturing conditions were used at the enrichment step in order to minimize copurification of proteins that are not ubiquitinated, but form complexes with ubiquitin. The enriched ubiquitinated proteins were digested with trypsin and analyzed by SCX/RP/MS/MS followed by identification by SEQUEST. The tryptic

digestion of ubiquitinated peptides results in glycine–glycine fragments at the sites of modification. The corresponding increase in mass by 114 Da of the modified lysine residues allows localization of the sites of ubiquitination. As a result, the authors identified 110 ubiquitination sites present in 72 ubiquitinated proteins. However, some of the known ubiquitinations were not detected. This is probably due to the fact that the method is biased toward more abundant species. Indeed, precise localization of a posttranslational modification via SEQUEST requires a high sequence coverage. As a consequence, in their analysis, Peng et al. identified 1075 proteins totally after Ni-resin purification, but were able to confirm ubiquitination in only 10% of them.

3.3 Analysis of Protein–Protein Interactions by Mass Spectrometry

In a cell, proteins exert their functions through interactions with other proteins. Proteomics methods developed in the past few years can be applied directly to the analysis of the protein–protein interactions and protein complexes. Protein–protein interactions can be studied either on the level of individual protein complexes, or on the level of the whole proteome. Examples of different types of analyses include the possibility of predicting interactions from amino acid sequence, focused mass spectrometric analyses of individual multiprotein complexes: yeast ribosome, SAGA-like complex (SLIK), Pol II preinitiation complex (PIC), nuclear pore complex (NPC), and proteome-wide analyses of protein–protein interactions. In addition, quantitative proteomic methods may be used to analyze the dynamics of protein complexes.

3.3.1 Computational Methods of Protein–Protein Interaction Prediction

To some degree, protein–protein interactions can be deduced indirectly from the amino acid sequences. In this pursuit, Bock et al. created a learning algorithm that was trained to recognize and predict protein–protein interactions. The training was achieved on the experimentally known interactions from a variety of organisms. As an outcome of the training, the decision function was constructed, which was statistically evaluated using unseen test data. As a result, on average, about 80% of the interactions were predicted accurately from the unseen datasets. Obviously, computational methods alone do not give exhaustive description and the obtained results need to be validated experimentally. Nevertheless, the interaction datasets obtained *in silico* provide useful reference points for experimental types of analyses.

3.3.2 Yeast 2-hybrid Arrays

One of the most common approaches to analyze protein–protein interactions is the yeast-2-hybrid (Y2H) screen, which is a selection method that detects protein–protein interactions in the yeast nucleus. This is a well-developed technique that can be easily optimized for a high-throughput analysis. The Y2H screen was successfully applied to mapping of a large-scale protein interaction network in the yeast *S. cerevisiae*. The Y2H has a good resolution and can detect weak and transient interactions. However, the Y2H method detects only binary interactions between proteins and may not be used to study transcriptional activators. Another drawback of the Y2H is that interactions occur in the nucleus, so that interactions for many proteins take place out of their native environment.

3.3.3 Direct Analysis of Large Protein Complexes; Composition of the Yeast Ribosome

Link et al. employed multidimensional liquid chromatography coupled with MS/MS to study composition of the yeast ribosome. The authors named their method *direct analysis of large protein complexes*, and demonstrated its wide applicability. In this study, the ribosomes were purified by sucrose gradients and then denatured. Next, the ribosomal RNA was removed, the ribosomes were enzymatically digested, and the digests were loaded on a 2D separation column, consisting of the SCX and the RP dimensions. After the separation, peptides were eluted directly into the mass spectrometer for the MS/MS analysis. Finally, SEQUEST algorithm was used to search nucleotide databases and to match the peptide fragmentation patterns. The authors demonstrated the high-throughput capacity of this approach – more than 100 proteins could be identified in a single experiment. As a result of this study, new protein components of yeast and human 40 S subunit were discovered.

3.3.4 Analysis of Multisubunit Protein Complexes Involved in Ubiquitin-dependent Proteolysis by Mass Spectrometry

In a number of reports, Deshaies et al. (and references therein) used MS-based strategies to characterize the composition of various protein complexes involved in proteolysis. The authors used sequential epitope tagging, affinity purification, and mass spectrometry (SEAM) to study regulation and function of SCF ubiquitin ligases. In the application of this method, SCF subunits Skp1 and Cul1 were C-terminally tagged with Myc epitope. Next, the cells expressing the tagged proteins were lysed, and the soluble fractions were affinity purified, digested, and analyzed by mass spectrometry. As a result, a total of 16 Skp1- and Cul1-interacting proteins were detected. Several of these proteins were not previously known, including Hrt1, Rav1, and Rav2. These new proteins were further subjected to SEAM and this led to identification of the new complex Rav1/Rav2/Skp1. Subsequently, it was found that Rav1/Rav2/Skp1 complex interacts with V_1 component of V-ATPase, the vacuolar membrane ATPase. In different studies by biochemical methods, the authors further determined that Rav1/Rav2/Skp1 regulates the assembly of V-ATPase from V_1 and V_0 domains.

The same group used multidimensional protein identification technology (MudPIT) to identify proteins that interact with the 26 S proteasome. As it was introduced in the previous sections of this chapter, MudPIT allows analysis of immunoprecipitated fractions without a gel separation step. Instead, the immunoprecipitated fractions are digested, and the peptide mixtures are separated in two dimensions (SCX and RP) followed by MS analysis. Using MudPIT, the authors identified every known subunit within affinity-purified 26 S proteasome, as well as one subunit that was not previously known. Additionally, a set of proteins potentially interacting with the proteasome (PIPs) was found. By immunoblotting methods, six of these PIPs were further confirmed to associate with the proteasome.

3.3.5 Proteomics of the Nuclear Pore Complex

MS-based protein identification is a useful tool that can efficiently determine the composition of a given multiprotein complex. However, this method by itself does not necessarily provide information on the complex's spatial architecture. Nor does it directly answer questions about the

multiprotein complex function. Therefore, when such questions arise, the mass spectrometric tools need to be complemented with other techniques, for example, immunoblotting, immunofluorescence, electron microscopy and so on. Several studies of the nuclear pore complexes (NPCs) that are discussed here give a good illustration of these types of integrative strategies.

In the early 1990s, studies by three-dimensional cryoelectron microscopy revealed the basic shape and architecture of NPCs in *Xenopus* nucleus. It was determined that NPCs are proteinaceous structures situated in the double membrane of the nuclear envelope. Estimated sizes of NPCs vary from ~125 MDa (*Xenopus*) to 66 MDa (*Saccharomyces*). NPCs have an eightfold rotational symmetry with the rotational axis normal to the nuclear envelope membrane and a twofold mirror symmetry with the symmetry plane parallel to the nuclear envelope membrane. Current research efforts are aimed at understanding the mechanism of the biological function of the NPCs – nucleotransport. To understand the NPC's function, it is useful to catalog all the protein components of NPCs in different organisms. Ideally, this should lead to testable hypotheses on how these components contribute to the overall structure and function of NPCs. Biological problems of this kind can be addressed by proteomics methods as was elegantly demonstrated for yeast and mammalian NPCs.

In the yeast study, Rout et al. prepared highly enriched fraction of NPC proteins, followed by separation on ceramic hydroxyapatite HPLC, which gave efficient recovery of the loaded proteins. Reverse-phase TFA-HPLC was used in parallel for resolution of the low molecular mass proteins from the NPC fraction. The next step in the separation involved SDS-PAGE with visualization of protein bands by copper staining. Subsequently, peptide mixtures were prepared from bands of interest via in-gel trypsin digestion followed by analysis by MALDI-MS. The peptide mass matching method was used to search nonredundant protein sequence database. Previously known nucleoporins were genomically tagged with a protein A epitope (ProtA), which allowed further immunolocalization by fluorescence microscopy. As a result of this study, the authors identified 29 nucleoporins and 11 transport factors and NPC-associated proteins. The authors also determined stoichiometry and position of each of the nucleoporins found within the NPC by quantitative immunoblotting and by immunoelectron microscopy. In the immunoelectron microscopy analysis, the ProtA-tagged proteins were labeled using gold-conjugated antibody, which aided visualization. On the basis of the deciphered architecture of the NPC, Rout et al. proposed a model of nucleotransport called a *Brownian affinity gating model*. The core idea of the proposed model is that translocation through the NPC occurs via diffusion: diffusive movements of the filamentous nucleoporins on the cytoplasmic face of the NPC exclude macromolecules that do not bind to them, but when the binding does occur (and that happens when a cargo molecule is associated with its transport factor), the residence time of the cargo at the NPC gate increases, which in turn facilitates the diffusion of the cargo into the nucleus.

In the mammalian study, Cronshaw et al. enriched NPCs fractions from rat liver nuclei by sequential solubilization. At each step of the enrichment, the authors used electron microscopy, SDS-PAGE, and immunoblotting to confirm that NPCs remained intact. After the enrichment, NPCs were treated with detergent, which

produced a solution of monomeric nucleoporins. The individual proteins in this nucleoporin mixture were separated by C4 reverse-phase chromatography followed by SDS-PAGE. Protein identification was performed using single-MS and MS/MS. In addition to previously known 23 nucleoporins, Cronshaw et al. identified six novel nucleoporins, and also four proteins containing WD repeats. One of these four WD-containing proteins was ALADIN, the gene mutated in Allgrove syndrome.

Spatial organization of a protein complex can be assessed by the cross-linking method. In this method, a protein complex is affinity-purified and then treated with a cross-linking agent, a chemical that introduces new covalent bonds between neighbor proteins. New bands, that appear on SDS-PAGE because of this treatment can be excised and identified by mass spectrometry. As a result, if a pair of the proteins gets cross-linked, this usually means that the two proteins are located close to each other within the complex. A good example of this strategy is the study by Rappsilber et al. in which the authors used cross-linking/MS method to deduce the spatial composition of the six-member subcomplex Nup84p of the yeast NPC. The authors emphasized generic applicability of this approach. One of the significant challenges in application of this method, however, is the choice of the proper cross-linking reaction condition – usually a number of different cross-linkers has to be screened, before the right degree of cross-linking is obtained. Additionally, interaction between subunits that are hidden deep inside a complex may be inaccessible to cross-linkers. Because of these and other difficulties, the cross-linking method is limited to complexes of small sizes and is difficult to apply on the broader scale. Nevertheless, the cross-linking method may prove to be useful in the studies of conformational or compositional changes of individual protein complexes, when the specific structural states can be ''frozen'' through interaction with the cross-linking agents.

3.3.6 High-throughput Analyses of Protein–Protein Interactions

In most cases, MS-based analytical schemes similar to those employed in the studies of individual complexes can be redesigned for use at the proteome-wide scale. A report by Gavin et al. is one of the first examples of the MS-based proteome-wide analyses of the protein complexes. For the large-scale isolation of the protein complexes from yeast Gavin et al. used tandem affinity purification (TAP), as first introduced by Rigaut et al. In the TAP method, a gene-specific fusion cassette – which contains calmodulin-binding domain, a specific protease cleavage site, and ProtA domain – is introduced at the C- or N-terminal of yeast's ORFs of interest. Then, assuming that expression of fusion proteins is maintained close to the natural level, the first affinity purification is performed. In this step, fusion proteins along with their interaction partners (so-called protein assemblies) are isolated from cell extract by affinity selection on IgG matrix. Next, the bound proteins are released by addition of the protease. Finally, the second affinity purification is done, which involves incubation with calmodulin beads in the presence of calcium. The advantage of tandem affinity purification when compared to standard epitope tagging approaches is that it removes most of the nonspecific interactions. Out of 1548 yeast strains generated by Gavin et al., 1167 expressed the fusion proteins at detectable levels. After the purification of the protein complexes by TAP, the authors

subjected the complexes to electrophoretic separation followed by trypsin digestion, and subsequent analysis by MALDI-MS. Overall, by MS analysis, Gavin et al. identified 1440 gene products (~25% of the genome) from various organelles. However, identification of membrane proteins in this study has proven to be difficult – only 40 membrane proteins were purified successfully out of total 293 membrane proteins detected. The authors then proceeded with grouping of the identified proteins into complexes. This was done by the analysis of overlaps in composition of the pulled-down assemblies from 589 different bait proteins. The authors reported a total of 245 purifications that corresponded to 98 known complexes from the yeast protein database (YPD). Another 242 purifications out of the 589 were assembled into 134 new complexes. The authors were able to identify proteins as low-abundant as 15 copies per cell, thus showing high sensitivity of the TAP method. However, reproducibility was rather poor – the authors estimated that probability of finding the same protein from the same bait in two purifications is about 70%. Another weakness of the TAP method comes from possibility of interference of the TAP tag with complexes assembly and protein function. In fact, Gavin et al. found that when the essential genes were TAP-tagged; in about 20% of these cases, nonviable strains were obtained. Also, the authors reported significant bias against proteins with molecular weight below 15 KDa.

Another notable report of a high-throughput protein complex identification is the study by Ho et al. In this case, the bait proteins contained Flag epitope tag and were overexpressed from *GAL1* or *tet* promoters. Next, the protein assemblies were isolated in one-step immunoaffinity purification followed by resolution on SDS-PAGE, digestion and MS, and MS/MS analyses. The authors called this method "high-throughput mass spectrometric protein complex identification" (HMS-PCI). The immunoaffinity purification of complexes assembled around overexpressed baits should, in theory, generate more false-positives than TAP method would generate, because of the nonphysiological concentrations of the baits. On the other hand, weak and transient interactions that would not be detected in the TAP method could be captured by HMS-PCI. In fact, Ho et al. were able to assess certain regulatory and signaling pathways, by studying complexes pulled-down with phosphatases and kinases used as baits.

As of today none of the methods of mapping of protein–protein interactions within a proteome is comprehensive enough to provide full coverage. Hence, it is useful to compare datasets obtained with different approaches. In their article, Christian von Mering et al. evaluated all available interaction datasets obtained in yeast. These included the data from MS-based studies discussed above, as well as data from Y2H, correlated mRNA expression, synthetic lethality, and *in silico* predictions. The evaluation was done through comparisons with the reference dataset (MIPS and YPD). As a result, percentage coverage (fraction of the reference covered) and accuracy (fraction of data confirmed by the reference) were estimated for every method. According to the authors' analysis, TAP method provides both higher coverage and higher accuracy than either Y2H or HMS-PCI. Also, the analysis shows that HMS-PCI is the least accurate method amongst the three.

In a series of reports, Bader and Hogue developed algorithmic approaches for finding molecular complexes from datasets

obtained in different interaction studies. By analyzing combined data from TAP and HMS-PCI studies, they found a novel nucleolar complex of 148 proteins that included 39 proteins with unknown function. Further, they described a graph-theoretic clustering algorithm *molecular complex detection* (MCODE) that allows detection of dense regions (potential complexes) within the interaction networks. Importantly, the authors showed that MCODE algorithm is not affected by a high rate of false-positives in datasets from the high-throughput experiments.

To summarize, none of the current high-throughput experimental schemes provide sufficient coverage and accuracy. Therefore, integrative approaches that take advantage of different methods are necessary. Additionally, all of the discussed cases dealt with cells in a certain growth conditions. It is of special interest, however, to study dynamics within protein interaction networks in response to environmental stimuli, in progression through the cell cycle, or in pathological states. Some of these questions can be addressed by quantitative proteomics techniques.

3.3.7 Quantitative Proteomics Methods in the Studies of Protein Complexes

Methods of quantitative proteomics can be used to study dynamical changes in abundance, composition, and activities of multiprotein complexes. A good example of such a study is the work by Ranish et al. in which composition of a large RNA polymerase preinitiation complex (PIC) was assessed by the isotopically coded affinity tags (ICATs) method. This and other differential labeling methods are discussed in detail in the previous section of this chapter. The ICAT approach as employed by Ranish et al., consists of the four major steps summarized below:

1. The samples from two different conditions are labeled with either ''light'' or ''heavy'' tags.
2. The labeled samples are combined together and enzymatically digested.
3. The mixture is fractionated by SCX chromatography, then the labeled peptides are isolated by avidin-affinity chromatography followed by separation by the reversed-phase microcapillary chromatography.
4. The labeled peptides that are eluting from the reversed phase column are analyzed by ESI-MS/MS.

In MS analysis, the peak intensity ratios of the differentially labeled peptides on the ion chromatogram are related to the relative abundances of the corresponding proteins in the two different environments. The peptide identities are established in the MS/MS spectra and the corresponding proteins are identified by SEQUEST. With this quantitative ICAT method, the authors were able to distinguish between components of the PIC and the copurifying background proteins, some of which had higher abundances. Thus, the authors demonstrated the high analytical power of this approach. In their analysis, Ranish et al. identified a total of 326 proteins, 42% of which participate in the Pol II-mediated transcription. Also, the authors used the ICAT method to monitor changes in the PIC composition in the presence or absence of TBP. TBP is a transcription factor that binds to the TATA element and is required for the functional PIC assembly. According to Ranish et al., most of the Pol II components are increased in abundance by a factor of at least 1.9 upon addition of TBP, and several Pol II components showed no increase in abundance. In addition, potentially new component of the PIC was discovered. A

limitation of this approach, as was noted by the authors, is that using only the cysteine specific tags leaves out tryptic peptides that do not contain cysteines. In this respect, strategies that use metabolic labeling or N-terminal labeling may be more promising.

As an example, in their recent paper, Blagoev et al. used stable isotopic amino acids in cell culture (SILAC) to study EGF signaling. The control and EGF-stimulated HeLa cell populations were labeled with ^{12}C- arginine and ^{13}C-arginine respectively via metabolic incorporation. Combined cell lysates from these two conditions were affinity-purified with SH2 domain of GST-SH2 fusion protein used as bait. SH2 domain specifically binds phosphorylated EGF receptor. Protein complexes obtained in this purification were digested with trypsin and the peptide mixtures were analyzed by MS. As a result, the authors identified 228 proteins, 28 of which were enriched upon EGF simulation.

Keywords

Basement Membrane (BM)
A highly ordered thin sheetlike sub-compartment of the ECM composed of networks of glycoproteins and proteoglycans that separate epithelia and endothelia from the underlying stroma.

Cryptic ECM Epitope
A specific amino acid sequence of an ECM protein that is normally not accessible for cellular interactions under normal physiological conditions.

Extracellular Matrix (ECM)
A complex acellular network of adhesive collagenous and noncollagenous glycoproteins embedded in a hydrated gel composed of a mixture of proteoglycans.

Interstitial Matrix
A loosely organized sub-compartment of the ECM composed of glycoproteins, proteoglycans, and matricellular proteins that surround individual cells and tissues.

Matricellular Proteins
ECM-associated proteins that modulate cellular functions but which do not contribute significantly to structural architecture of the matrix.

The requirement of bidirectional communication between cells and their local acellular microenvironment for proper development and homeostasis in multicellular organisms has been appreciated for decades. Interestingly, intriguing new studies have suggested that some of this molecular information may be cryptic or hidden within the three-dimensional architecture of proteins and requires structural modification of the ECM for efficient transmission and utilization by cells and tissues. Thus, the dynamic interplay between cells and both intact and structurally altered ECM proteins help establish specificity, coordinate, and refine the complex interconnected biological responses critical for normal physiological processes. In this regard, unique insight will likely be gained into pathological events by a more complete understanding of the integrated network of molecular signals regulated by cellular interactions with the ECM.

1 Introduction

It has been known for decades that multicellular organisms depend on information within the local acellular microenvironment for proper structural organization, development, and homeostasis. The complex interconnected networks of molecules that compose the extracellular environment impacts nearly every aspect of normal physiology and disease, ranging from molecular control of gene expression and cell cycle progression to mechanical and architectural organization of tissues and organs. The major interests of many early investigators within the fields of molecular and developmental biology were primarily focused on the cellular compartment, including membrane, cytoplasmic, and nuclear components. However, as more sophisticated technology and tools were developed, it quickly became apparent that cells were not only physically linked to the insoluble scaffolding proteins outside the cell, but that cell shape, function, and survival depended on unique interactions and the bidirectional flow of information from outside the cell to the cells interior. Thus, the stage was set to begin the fascinating journey into an in-depth understanding of the biological responses controlled by the extracellular matrix (ECM).

2 Structural Organization and Molecular Composition of the Extracellular Matrix

For the purpose of our discussion, the ECM can be thought of as being composed of two general compartments, including the basement membrane (BM) or basal lamina and the interstitial matrix (Fig. 1). While these two compartments can be studied as separate features, they do not exist in isolation, but rather are interconnected by a variety of anchoring and

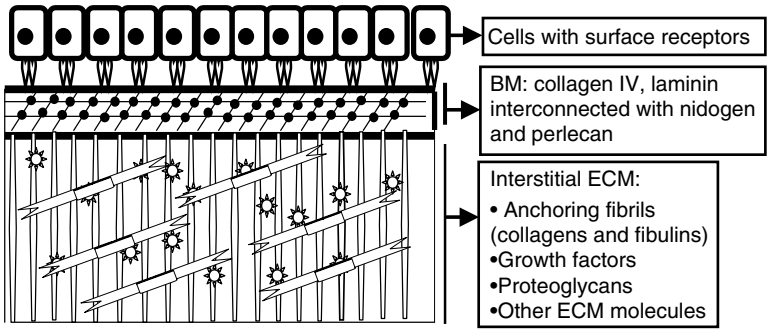

Fig. 1 Schematic representation of the structural organization and composition of ECM. The extracellular matrix can be organized into two compartments, including the basement membrane (BM) and the interstitial matrix. These two compartments are connected by a series of anchoring fibers, which consist of distinct forms of collagen, fibulins, as well as other ECM macromolecules. The major components of the BM include collagen type IV, laminin, nidogen, and perlecan. The interstitial matrix is composed of a gel-like composition of ECM proteins, including fibronectin, distinct forms of collagen, vitronectin, and various matricellular proteins such as thrombospondin. Growth factors, proteases, and a number of proteoglycans can also be found in the interstitial matrix.

interconnecting fibrils. Thus, a highly integrated continuum exists between the BM and interstitial matrix. In general terms, the BM is organized into a highly ordered meshlike network composed of structural glycoproteins, proteoglycans, and other macromolecules. BMs can be found underlying mostly all epithelial sheets and blood vessels, thus contributing to physical and functional compartmentalization. In contrast, the interstitial matrix can be characterized as a loosely organized gel-like composition of collagenous and noncollagenous glycoproteins, proteoglycans, and matricellular proteins that surround cells, tissues, and organs. The molecular composition of the BM and interstitial matrix can vary widely, depending on the repertoire of cells present within a given tissue. Moreover, the composition and structural integrity can also vary, depending on the particular physiological and/or pathological processes that may be occurring at any given time.

While heterogeneous in composition, examples of the major components of the BM include collagen type IV, laminin, nidogen, and perlecan. In addition to cross connections mediated by nidogen, collagen, and laminin, these molecules can interact with each other via a number of unique functional domains. While these macromolecules make up the majority of the BM, other minor, but no less important, components contribute to its structure, including genetically distinct forms of collagen (i.e. collagen type VIII, XV, and XVIII) and numerous proteoglycans. Examples of the major components of the interstitial matrix include an array of fiber forming collagens, including collagen type I, II, and III. Other major components that have been characterized include fibronectin, vitronectin, fibrinogen, thrombospondin, and elastin (Table 1).

Elastin

The complex sets of matrix macromolecules are not randomly organized, but are specifically ordered and arranged into supramolecular assembles. The physical interactions that facilitate the unique architectural organization are mediated, in large part, by distinct protein–protein binding domains, glucosaminoglycan (GAG) side chains, and a variety of carbohydrate moieties. For example, distinct functional domains found within nidogen bind collagen, and laminin, while unique domains within collagen can self-associate with other collagen molecules as well as other ECM proteins. These structural glycoproteins and proteoglycans also provide functional binding sites for a variety of growth factors, cytokines, proteolytic enzymes, and cell adhesion receptors. Thus, it is clear that besides participating in the structural assembly of mechanical scaffolds, ECM molecules facilitate localization and storage of a number of crucial regulatory factors. ECM localization of these regulatory molecules may serve to

protect them from degradation and/or induce conformational changes necessary for optimal presentation to cell surface receptors. As can be appreciated from the vast complexity of protein–protein interactions, it would be well beyond the scope of our discussion to analyze in-depth the vast number of molecular association that contribute to the assembly of the ECM.

While it was once thought that the ECM was merely an insoluble scaffold that primarily functioned in providing mechanical support for cells and tissues, it is now known that the ECM can regulate a variety of processes. Some of the more well-characterized events (Fig. 2) regulated by the ECM include adhesion, migration, invasion, cell cycle progression, proliferation, cell survival, differentiation, gene expression, tissue compartmentalization, and filtration. The ECM is not simply a static structural scaffold, but is rather dynamic, with changes occurring in molecular composition and structure. This dynamic feature is critical in helping to integrate the complex sets of regulatory signals transferred to cells from the ECM. In fact, fine-tuning these matrix-derived signals can be accomplished by structurally altering matrix components, which may modify existing binding sites for growth factors, cytokines, proteases, and cell surface receptors. Conformational changes in matrix molecules may expose new cryptic binding sites for secreted molecules along with creating novel binding sites for cell surface receptors such as integrins. Notably, the compositional and structural changes occurring within the ECM can be facilitated by changes in the secretion, structural organization, glycation, and cross-linking of proteins. The wealth of biochemical and molecular information stored within the ECM can be

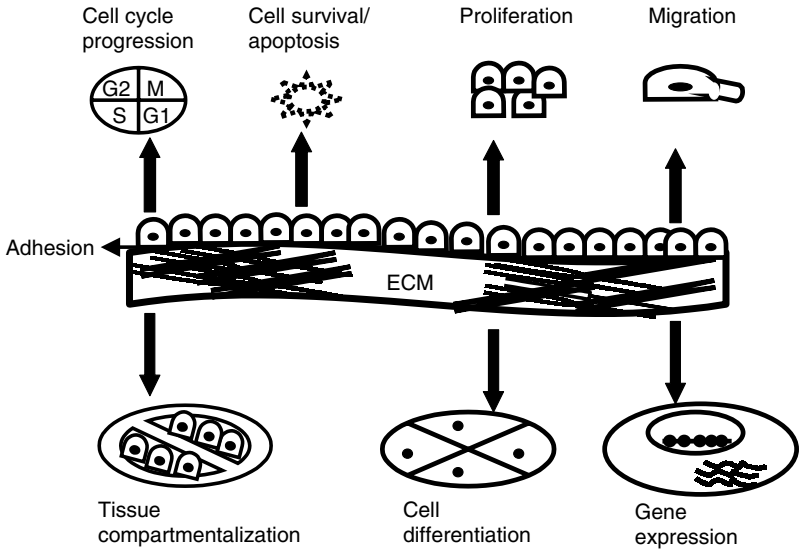

Fig. 2 Cellular processes regulated by the ECM. Cellular interactions with the extracellular matrix can regulate a wide array of important cellular processes. A partial list of the well-characterized events include cell cycle progression, cell survival, and apoptosis, proliferation, migration, adhesion, tissue compartmentalization, differentiation, and gene expression.

transmitted to the cells by binding to a number of cell surface receptors, including integrins, cell surface proteoglycans, and an emerging class of receptor tyrosine kinases. While examples of all these classes of receptors have been shown to mediate cellular interactions with the ECM, it could be argued that integrins are the most well-studied group of molecules that mediate cell–ECM interactions.

2.1 Molecular Composition and Structural Organization of the Basement Membrane

As mentioned above, the BM or basal lamina is a highly ordered meshlike network of glycoproteins and proteoglycans that separate epithelium and endothelium from the underlying stroma. Given the diversity of cell types that secrete ECM molecules, it is not surprising that the molecular composition of BMs can vary from tissue to tissue. While molecular diversity is evident, a number of major components are common to most BMs and include collagen type IV, laminin, nidogen, and perlecan. These molecular components are not meant to represent a complete list of the BM molecules, but rather, examples of well-characterized components to help illustrate its compositional and structural organization.

2.2 Collagen Type IV

The major collagenous component of the BM is collagen type IV. A variety of other minor collagen types are also present, including collagen types VIII, XV, and XVIII. Collagen type IV molecules are composed of a combination of 3 α chains organized in a triple helical manner. Six different collagen type IV chains ($\alpha1$–$\alpha6$) have been identified, each of which represents a distinct gene product. One of the most widely distributed isoforms of collagen type IV present in nearly all BMs is the triple helical molecule composed of 2 $\alpha1$(IV) chains and 1 $\alpha2$(IV) chain. Interestingly, other isotypes of type IV collagen have been detected in the BMs from distinct tissues, suggesting tissue-specific distribution patterns. Collagen type IV is organized into functional domains, including a large central triple helical region composed of repeating units with glycine at every third position. While this repeated pattern and triple helical structure exists throughout the central domain, interruptions on this unique organization also exist. The triple helical region has been shown to be critical for mediating cell adhesion, as a number of integrin-binding sites have been localized to this area. Moreover, several binding sites for other ECM proteins are also located within the triple helical region, suggesting an important role for this region in the collagen network assembly. The amino terminus of collagen type IV contains a globular region termed the *7S domain*. The 7S domain facilitates association of collagen molecules into tetramers, which is important in the formation of higher-order collagen networks. A third important structural and functional feature is the C-terminal globular noncollagenous (NC1) domain. These NC1 domains are thought to facilitate selection of individual α chains during network assembly. Interestingly, recent studies have indicated that specific integrin-binding sites are not only confined to the triple helical domain but are also located in NC1 domains. For example, studies have indicated that the NC1 domain from $\alpha1$ chain can interact with integrin $\alpha1\beta1$, while the NC1 domain from the $\alpha2$ chain supports interactions with integrins $\alpha3\beta1$, $\alpha v\beta3$, and $\alpha v\beta5$.

Moreover, NC1 domains from the $\alpha 3$ and $\alpha 6$ chains of collagen type IV specifically bind to integrin $\alpha v\beta 3$, while NC1 domains form $\alpha 4$ and $\alpha 5$ chains fail to interact with integrin receptors. Given the facts that ligation of distinct integrin receptors can initiate unique signaling cascades, integrin interactions with noncollagenous (NC) domains may regulate a diversity of cellular processes. To this end, it is becoming increasingly clear that NC1 domains from distinct forms of collagens, such as types IV, VIII, XV, and XVIII, may possess unique regulatory properties since potent antiangiogenic and antitumorgenic modules have been identified from these regions.

Several families of molecules have been shown to mediate cellular interactions with collagen (18–20, 29, 30). However, integrin receptors likely represent the predominate class of cell surface molecules, facilitating interactions with collagen type IV. A number of distinct integrin heterodimers interact with triple helical collagen IV, including integrins $\alpha 1\beta 1$, $\alpha 2\beta 1$, and $\alpha 3\beta 1$. During invasive cellular events, such as tumor invasion, metastasis, and angiogenesis, the triple helical structure of collagen can be altered, leading to disruption of $\beta 1$ integrin binding, resulting in exposure of cryptic $\alpha v\beta 3$ bindings sites. This shift in integrin-mediated recognition could result in the initiation of unique signaling cascades. Thus, minor changes in the three-dimensional structure of collagen could profoundly impact signaling cascades, thereby modifying the biological response to the ECM.

2.3 Laminin

A second large glycoprotein that forms an interconnected sheetlike network with collagen type IV is laminin. Laminin represents a family of adhesive glycoproteins comprised of high molecular weight (about 800 kDa) disulfide-linked heterotrimers with chains designated α, β, and γ. Since the original discovery of laminin many years ago, five different α-chains ($\alpha 1$ to $\alpha 5$), three different β chains ($\beta 1$ to $\beta 3$), and three different γ-chains ($\gamma 1$ to $\gamma 3$) have been identified. Although the theoretical combinations of the three individual chains could allow up to 45 different trimeric isoforms, to date 12 isoforms have been described in detail. Of the 12 isoforms known, it could be argued that laminin-1 ($\alpha 1\beta 1\gamma 1$) and laminin-5 ($\alpha 3\beta 3\gamma 2$) are perhaps the most well characterized. The individual chains of laminin share a significant degree of structural similarity, and can be organized into a number of functional domains, including globular domains (IV and VI), epidermal growth factor (EGF)-like laminin-repeats (LE-module) (III and V), and an alpha-helical coiled-coil domain.

In general, laminin is organized into a crosslike structure containing three short arms and one long arm. The short arms are formed by the N-terminal region of one of the three chains, whereas the long arm is a rod-like coiled-coil structure comprised of the carboxyl termini of all three subunits. The long arm ends in a globular structure called the *G-domain*. The G-domain can be further subdivided into five globular subdomains (G1–G5). The G-domains contain major binding-sites for cellular receptors, such as integrins, syndecans, and α-dystroglycan. Moreover, laminin also possesses binding sites for minor collagen species such as collagen type XVIII. In addition to a number of proteoglycans, the BM protein nidogen directly interacts with laminin. Many of these unique protein–protein interactions

are thought to be critical for structural assembly of the BM.

While distinct forms of laminin are found mainly in the BM, studies have also identified isoforms present within the matrix of embryonic mesenchyme, loose connective tissue, and developing central nervous system. Interestingly, throughout embryonic development and in the adult organisms, studies have identified different patterns of cell and tissue-specific expression. In fact, distinct isoforms of laminin have their own temporally and spatially regulated expression profiles. For example, while laminin-10 exhibits wide tissue distribution, the expression of other isoforms is tightly regulated. In fact, laminin-2 is expressed in the BM of skeletal muscle and plays a role in neurite out growth, while laminin-5 is a constituent of the BM of many epithelial tissues where it regulates stable adhesion and promotes migration. Thus, it is clear that interactions with laminin can regulate a variety of cellular and physiological processes.

Laminin interacts with cells through a variety of mechanisms, including proteoglycans and integrin receptors. The major integrins known to interact with laminin include $\alpha 1\beta 1$, $\alpha 2\beta 1$, $\alpha 3\beta 1$, $\alpha 6\beta 1$, $\alpha 6\beta 4$, $\alpha 7\beta 1$, whereas examples of nonintegrin receptors include the 67-kDa laminin receptors and dystroglycan. Recent studies have suggested that laminin the $\alpha 4$ chain is a specific high affinity ligand for the $\alpha v\beta 3$ and $\alpha 3\beta 1$. Notably, distinct integrin binding sites have been identified within laminin, including the classical RGD amino acid recognition sequence as well as a number of non RGD integrin binding sites. As was seen with collagen type IV, the molecular and structural integrity of laminin can impact integrin recognition and modify cellular responses. For example, studies have identified a cryptic site exposed following proteolytic cleavage of laminin-5 that promotes breast carcinoma cell migration.

2.4 Nidogen

As discussed above, the two major structural glycoproteins collagen type IV and laminin are organized into two sheetlike networks. These complex meshlike assemblies are interconnected by the protein Nidogen. Nidogen, also known as *entactin*, is a ubiquitous component of the BM and is conserved in all metazoans. Interestingly, invertebrates, including *Caenorhabditis elegans*, possess only a single gene, whereas in mammals, two nidogen isoforms have been identified termed *nidogen-1* (150 kDa) and *nidogen-2* (200 kDa). Nidogen-2 is predominately located in endothelial BM, whereas nidogen-1 can be ubiquitously distributed within the basal lamina from a variety of tissues. These tissue distribution patterns suggest that different forms of nidogen may play distinct roles in tissue organization, BM assembly, and in the regulation of physiological processes such as blood vessel development. Studies have indicated that nidogen-2 binds to endostatin, an antiangiogenic module of the NC1 domain of collagen type XVIII (41). The two nidogen isoforms share substantial domain and sequence identity with an overlapping binding repertoire for laminins, collagen IV, perlecan, and fibulin. Nidogen consists of three globular domains (G1 to G3). Domain G2 of nidogen-1 contains the binding site for collagen IV, perlecan, and fibulins. In contrast, domain G3 contains high affinity binding sites for the laminin γ chain, collagen IV, and weaker binding sites for fibulins.

Studies have suggested that nidogen may play an important role in BM organization by facilitating connections between laminin and collagen IV networks. Interestingly, *C. elegans*, harboring mutant forms of nidogen-1, exhibited relatively normal assemble of type IV collagen, suggesting that nidogen-1 may not be essential for type IV collagen assembly under these conditions. These findings are somewhat surprising, given the previous studies indicating the importance of nidogen in the structural organization of collagen IV and laminin networks. The nidogen-binding site within laminin has been localized to the laminin epidermal growth factor–like (LE) module γ1III4. Antibodies against γ1III3-5 modules were shown to disrupt early kidney, lung, and salivary gland development. In addition to nidogen's function in stabilizing the BM, it has also been implicated in other protein integration functions such as facilitating interactions with ECM components such as perlecan and fibulin. As with many ECM proteins, nidogen plays roles in signal transduction through integrins $\alpha v\beta 3$ and $\alpha 3\beta 1$, thereby influencing the biological response of the cells to the ECM.

2.5 Perlecan

Besides the major glycoprotein components of the basal lamina, a second family of molecules that contribute to the formation of the BM includes the proteoglycans. Proteoglycans are not only important components of the ECM but are also found on the cell surface. Proteoglycans can be characterized as consisting of a core protein with negatively charged polysaccharide glucosaminoglycan (GAG) side chain. On the basis of their GAG side chains, proteoglycans can be classified into four main groups, including chondrotin sulfate, dermatan sulfate, keratin sulfate, and heparan sulfate. The cellular and tissue distribution profiles along with their biological functions have been suggested to depend on both the GAG chain and the core protein content. Interestingly, the GAG side chains attached to the core proteins have been shown to vary depending on the tissue. For example, phosphacan, a chondroitin sulfate proteoglycans expressed abundantly in neural tissue contains keratin sulfate in rat embryonal cerebellum, but lack these GAGs in rat retinal tissues. Thus, variations in the structural features of these molecules may modify their functions, and thus alter cellular behavior in a tissue-specific manner.

In addition to the structural diversity associated with the GAG chains, the core proteins also consist of structurally distinct domains. In fact, proteoglycans can interact with various biologically active molecules through specific domains of the core protein, thus expanding their diverse capacity to impact biological responses. Recent studies have identified more than 30 structurally distinct proteoglycans from vertebrate tissues. Many proteoglycans bind several different ECM components and growth factors, and play critical roles in processes such as cell adhesion, migration, and differentiation. Notably, heparan sulfate proteoglycans can be subclassified as those present on the cell surface, such as syndecan, those anchored to the cell surface by glycosylphosphatidylinositol such as glypican, and those present in the BM, including perlecan and agrin.

Perlecan is a multidomain heparan sulfate proteoglycan with a wide distribution in the ECM. Perlecan has been shown to be an important element for assembly

and function of BMs. Mammalian perlecan consists of a 480-kDa core protein containing three to four heparin sulfate or chondroitin sulfate side chains. The molecular weight of the fully glycosylated protein is between 700 and 800 kDa. Structural studies have provided evidence that perlecan consists of five distinct domains. Domain I, has a molecular weight of 20 kDa and consists of 172 amino acids containing three consecutive Ser-Gly-Asp triplets that represent the attachment sites for GAGs. Domain II of mammalian perlecan is homologous to the low-density lipoprotein (LDL) receptor ligand-binding domain and contains the pentapeptide DGSDE. While domain III is homologous to the internal segments of laminin A, domain IV is homologous to neural cell adhesion molecule (N-CAM). Domain V is located at the C-terminus and consists of tandem arrays of three laminin G-type modules and four epidermal growth factor–like modules. This domain can bind to the laminin–nidogen complex, fibulin-2, sulfatides, β1 integrins, and α-dystroglycan, thereby contributing to the BM organization and structure. Domain V also contains two SGxG tetrapeptides, which may serve as attachment sites for GAG chains other than heparan sulfate. In addition, this domain contains two Leu-Arg-Glu tripeptides that may facilitate binding of neurons to S-laminin in the synaptic BM. Finally, perlecan interacts with collagen type IV and fibronectin, further implicating it in the structural organization of the ECM.

Perlecan is produced during early and late stages of embryonic development and is localized in BMs, vessel walls, cartilage matrix, and other extracellular spaces. The importance of perlecan to mammalian development has been demonstrated in mouse knockout experiments. Although the BM can develop in the absence of perlecan, nearly half of all perlecan null mice died at embryonic day 10.5 with widespread cephalic, skeletal abnormalities, and aberrant BM formation in the heart. Studies have indicated that perlecan can regulate a variety of biological functions. Some of these well-characterized functions include its role in maintenance of the integrity of BM, and the storage of growth factors and cytokines within the ECM. Interestingly, proteolytic cleavage of perlecan may result in the release of proangiogenic factors such as fibroblast growth factors and/or antiangiogenic factors such as endorepellin, a newly identified antiangiogenic fragment of perlecan.

3 Molecular Composition and Structural Organization of the Interstitial Matrix

The ECM can be viewed as being composed of two compartments, including the BM and the interstitial matrix. While the general architecture of the BM is identifiable as a thin highly organized sheetlike structure. The interstitial matrix can be described as a loose organization of collagenous and noncollagenous glycoproteins, matricellular proteins, and proteoglycans that surrounds individual cells, tissues, and organs. It is important to note that while these compartments can be viewed separately, they are indeed intimately connected by anchoring fibers of collagen and fibulins. The components of interstitial matrix from a given microenvironment can vary, depending on the cellular repertoire of the tissue. Given the diversity of cell types that secrete ECM molecules, it would be well beyond the scope of our discussion

to attempt to describe in-depth all the components that contribute to the interstitial matrix. Thus, we have chosen to focus on a few examples of the major components, including collagen type I, the glycoproteins fibronectin, vitronectin, and the matricellular protein thrombospondin. These molecular components are not meant to represent a complete list of interstitial matrix molecules, but rather are examples of well-characterized components to help illustrate the composition, structural organization, and function of the interstitial matrix.

3.1 Collagen

The great importance of collagen in physiology, development, and tissue homeostasis has been known for decades. Its singular importance in all metazoan organisms is evident, given its high degree of conservation throughout species as diverse as sponges and man. Over the past several decades, a wealth of biochemical and genetic studies have demonstrated critical roles for collagen in structural organization and function of the ECM. In fact, a wide array of human diseases have been linked to aberrant synthesis, mutations, and biochemical modification of collagen, including Osteogenesis Imperfecta, Ehlers-Danlos Syndrome type V11, and Alport Syndrome, to name just a few. Collagen represents the most abundant ECM protein in the body. It has been estimated that at least 30 distinct genes code for specific α chains of collagen. In fact, at least 21 genetically distinct forms of collagen have been identified. The numerous forms of collagen can be grouped according to their general molecular structure, organization, and function, which include fibrillar collagens, nonfibrillar network forming collagen, FACIT (fibril-associated collagens with interrupted triple helices) collagen, and multiplexes. Examples of the multiplexin subgroup include collagen type XV and XVIII. Interestingly, these types of collagen have received much attention recently due to the discovery of potent antiangiogenic activity within isolated fragments (Restin and Endostatin) of their respective NC domains. As described above, collagen type IV is an important example of the nonfibrillar networking forming collagen, while collagen type IX and XII are examples of FACIT collagens. Some of the earliest forms of collagen to be described belong to the fibrillar collagen subgroup such as collagen type I, II, and III.

It has been estimated that collagen type I may represent up to 25% of the total protein in the body and the majority of the protein within the interstitial matrix. Therefore, we have chosen to focus on collagen type I as an example of a major collagenous protein within the interstitial matrix. Collagen type I is composed of three α chains, including two $\alpha 1$ chains and one $\alpha 2$ chain organized into a triple helical structure. These collagen type I chains exhibit the characteristic amino acid triplet repeat G-X-Y with Glycine (G) at every third position. The amino acids proline and hydroxyproline are also often represented at the X and/or Y positions within the triplet. The relatively small size of the glycine residue at the third position has been suggested to be critical for proper folding of the triple helical structure. Secretion of procollagen is followed by cleavage of both the N- and C-terminal propeptides. N- and C-terminal propeptide processing is crucial in facilitating collagen fibril formation and higher-order supra molecular assemblies. Interestingly, soluble propeptide fragments have been

detected in serum, and these correlate with enhanced collagen synthesis and bone metastasis. Moreover, propeptide collagen fragments have also been shown to exhibit a number of biological activities, including promoting chemotactic activity as well as inhibiting collagen synthesis under specific conditions. Thus, the maturation and synthesis of collagen type I appears to regulate a number of cellular processes.

Similar to what was discussed with other ECM molecules, collagen type I can interact with a variety of proteins, including other ECM molecules such as fibronectin, thrombospondin, secreted protein acidic rich in cysteine (SPARC) and a number of proteoglycans. These distinct protein–protein interactions can be altered by structural and biochemical changes, including altered hydroxylation, cross-linking, glycation, and the degree of triple helical formation. For example, structural denaturation of the triple helical region can expose unique cryptic binding sites for additional molecules. Moreover, collagen interactions with distinct proteoglycans such as decorin have been shown to specifically alter collagen structure, fibril, and matrix formation. In addition, collagen type I can interact with many other molecules, including proteolytic enzymes and cell surface receptors such as integrins, which facilitate communication between cells and the matrix. The major integrin receptors mediating cellular interactions with collagen include members of the $\beta 1$ integrin subfamily such as $\alpha 1\beta 1$ and $\alpha 2\beta 1$. Shifts in integrin interactions with collagen may result in the initiation of unique signaling pathways, leading to alterations in biological responses, including cell adhesion, migration, proliferation, survival, and gene expression.

3.2 Fibronectin

The large glycoprotein fibronectin is a multidomain molecule found in the ECM, on the surface of cells, and in plasma and other body fluids. Fibronectin can exist in multiple soluble and insoluble forms. Soluble forms of fibronectin represents a major component in the plasma and other bodily fluids, while insoluble forms are either associated with the cell surface or are incorporated into the interstitial matrix. The fibrillar form of fibronectin is of considerable interest to the present discussion because of its capacity to mediate an array of interactions with other ECM proteins. In particular, this multidomain glycoprotein exists as a dimer composed of a two 250-kDa monomers linked covalently near the C-termini by a pair of disulfide bonds. Each monomer is comprised of multiple regions termed *fibronectin type repeats*. Fibronectin is organized into multiple domains containing 12 type I, 11 type II and 15 to 17 type III repeats.

The complex structural organization of fibronectin helps facilitate interactions with a variety of molecules. For example, fibronectin contain binding sites for fibrin, native and denatured collagens, heparin and a number of growth factors. Interestingly, recently studies have indicated that fibronectin type II modules can interact with collagen types II, III, IV, V, and X. Moreover, fibronectin also contains heparin-binding domains that interact with heparin and chondroitin sulfate proteoglycans. Fibronectin type III repeats can bind to the matricellular protein tenacin. Taken together, these observations imply that the biological activities of fibronectin involve a number of critical interactions with a broad range of molecules.

Besides providing critical binding sites for many components of the interstitial matrix, fibronectin is well known for its capacity to facilitate cell adhesion, migration, proliferation, and cell survival. These important cellular processes are regulated in large part by integrins. Examples of the integrins known to bind to fibronectin include $\alpha5\beta1$, $\alpha4\beta1$, $\alpha9\beta1$, $\alpha4\beta7$, $\alpha v\beta3$, and $\alpha v\beta6$. One of the most common integrin receptors for fibronectin is $\alpha5\beta1$, which binds to fibronectin repeats I_{1-9}, $II_{1,2}$, III_9, and III_{10}. Importantly, the ability of fibronectin to facilitate cellular interactions mediated by multiple integrin binding events provides an opportunity to initiate distinct signaling cascades.

3.3 Vitronectin

Another important glycoprotein associated with the interstitial matrix is vitronectin. Vitronectin is a 75-kDa adhesive glycoprotein that is present in both the plasma and the ECM. It circulates in blood in a monomeric (native) form, but is converted into disulfide-linked multimeric (denatured) form when incorporated into the ECM. The native vitronectin molecules contain 459 amino acid residues organized into functionally distinct domains. The N-terminal domain (residues 1–44) of vitronectin is rich in cystine and is termed the *somatomedin B* (SMB) domain. Importantly, the well-known integrin recognition sequence Arg-Gly-Asp (R-G-D) is located in the C-terminus of the SMB domain residues. The most C-terminal portion (residues 348–370) of vitronectin contains sequences homologous to hemopexin and has a positively charged heparin-binding segment.

Although vitronectin is predominately produced in the liver and found in the circulation, it is also found in a variety of tissues, particularly during wound healing, inflammation, angiogenesis, and during tumor growth. Interestingly, some of the unique protein-binding properties of vitronectin depend on its structural conformation and degree of multimerization. For example, multimeric forms of vitronectin exhibit enhanced capacity to bind to a number of molecules, including other ECM proteins and specific proteoglycans. Moreover, vitronectin has been shown to interact with growth factors and growth factor–binding proteins present within the ECM such as transforming growth factor-β (TGFβ) and insulin-like growth factor–binding protein-5 (IGFBP-5). Vitronectin binding to IGFBP-5 may act to modulate its bioavailability, thus impacting the function of insulin-like growth factor-1 (IGF-1), which in turn could alter cellular migration and proliferation. Adding to the diversity of molecules known to interact with vitronectin include factors such as the C5b-8 complement complex, the thrombin-antithrombin III complex, plasminogen activator inhibitor 1 (PAI-1), urokinase plasminogen activator receptor (uPAR), heparin, plasminogen, and β-endorphin. Vitronectin has also been shown to regulate cell adhesion, migration, proliferation, and cell survival. The vast majority of these cellular functions are regulated by integrins. The major integrin receptors known to interact with vitronectin include the classical vitronectin receptor $\alpha v\beta3$ as well as a variety of other αv-containing integrins such as $\alpha v\beta1$, $\alpha v\beta5$, $\alpha v\beta6$, and $\alpha v\beta8$. Again, the variety of signaling pathways initiated by distinct integrin ligation events can serve to coordinate, transmit, and regulate cellular responses associated with vitronectin.

3.4 Thrombospondin

A number of matricellular proteins are also important components of the interstitial matrix. Matricellular proteins have been defined as those ECM-associated proteins that modulate cell–ECM interactions and/or cellular functions, but which do not contribute significantly to the structural architecture of the matrix. Some examples of well-characterized matricellular proteins include tenacin, osteopontin, thrombospondin, and SPARC. We have chosen to focus primarily on thrombospondin as one example of the important matricellular protein family.

Members of the thrombospondin family can be subdivided into at least two groups on the basis of their general structure and domain organization. For example, thrombospondin-1 (TSP1) and thrombospondin-2 (TSP2) are trimeric molecules, which contain a procollagen-like domain and type 1, and type III repeat (TRS) domains. In contrast, TSP3, TSP4, and TSP5 are pentameric molecules, which lack the procollagen-like domain. In general, members of the thrombospondin family can be characterized as multimeric, calcium-binding glycoproteins that regulate a variety of cellular functions. As an example, thrombospondin-1 is a 420-kDa homotrimeric glycoprotein, which contains N- and C-terminal globular domains. The N- and C-terminal globular domains interact with heparin, and heparin sulfate proteoglycans along with facilitating cell attachment, spreading, migration, and platelet aggregation. The procollagen-like domain plays a role in subunit assembly along with exhibiting the capacity to inhibit angiogenesis, while the type III repeat facilitates both calcium and cell binding. While this multifunctional protein can interact with other ECM molecules such as heparin sulfate proteoglycans, it is not considered to play a major role in structural organization of the interstitial matrix. Thrombospondin is secreted by a variety of cells, including macrophages, fibroblasts, and endothelial cells, and is distributed within a variety of tissues. Interestingly, in the adult organism, thrombospondin has been observed predominately at sites of injury and tissue remodeling.

As has been observed with most ECM proteins, thrombospondin can interact with a variety of distinct proteins, thereby playing roles in the regulation of many cellular processes. The functions of TSP1 are thought to be mediated by direct binding to cell surface receptors, including integrins. In fact, TSP1 binds to a number of integrins such as, $\alpha v\beta 3$, $\alpha IIb\beta 3$, $\alpha 3\beta 1$, $\alpha 4\beta 1$, and $\alpha 5\beta 1$. Moreover, a number of nonintegrin-binding proteins or receptors have also identified, including the low-density lipoprotein receptor-related protein (LRP), proteoglycans, CD36, and CD47. Beyond the ability of thrombospondin to interact with cell surface receptors, studies have revealed a complex array of other binding proteins ranging from other ECM molecules such as fibrinogen, fibronectin, and heparin sulfate proteoglycans to a variety of proteases, including thrombin, elastase, and certain MMPs. Given the capacity of thrombospondin to interact with such a diversity of distinct protein, it is not surprising that it has been shown to regulate many important cellular events, including attachment, spreading, motility, cytoskeletal organization, proliferation, cell–cell aggregation, apoptosis, transcriptional regulation, differentiation, and angiogenesis. Thus, as can be clearly appreciated from the relatively short discussion of thrombospondin,

this ECM protein plays major roles in regulating a diversity of biological responses to the interstitial ECM.

4 Cellular Receptors for ECM Components

The ability of cells to respond to their extracellular environment depends on bidirectional communication with stromal elements. In fact, this bidirectional flow of information is crucial to the development and homeostasis of multicellular organisms. Thus, to detect, integrate, and transmit information from outside the cell to the inside and, in turn, to respond to specific microenvironmental changes, cells need a network of unique sensor and responder-type receptor molecules with the capacity to assimilate, organize, and use the information within the ECM. To this end, at least five families of cell adhesion receptors have been identified with the ability to mediate either cell–cell or cell–ECM interactions (Fig. 3). The major groups of cell adhesion molecules include selectin, cadherins, members of the immunoglobulin super gene family, cell surface proteoglycans, and integrins. Interestingly, recent studies have also identified an emerging group of receptor tyrosine kinases that may facilitate cellular interactions with the ECM. These groups of cell adhesion receptors have the capacity to transmit biochemical and molecular information from the stromal environment. With some exceptions, the members of the selectin, cadherin, immunoglobulin, and proteoglycans families mediate cell–cell interactions, while integrins are

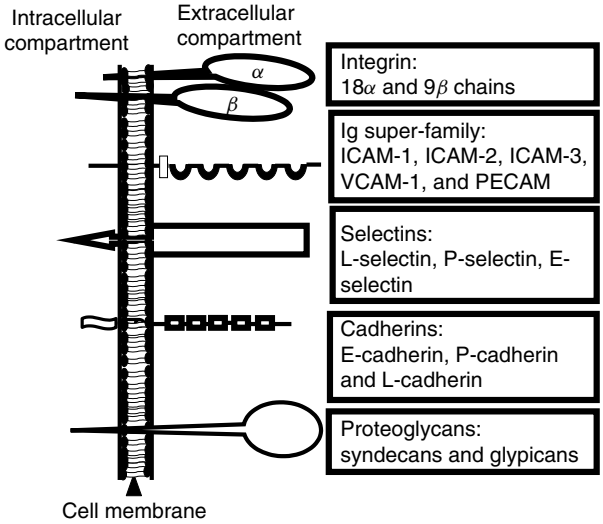

Fig. 3 Major families of cell adhesion molecules mediating cell–cell and/or cell–ECM interactions. In order for cells to sense and, in turn, respond to the acellular microenvironment, they require cell surface receptors with the capacity to facilitate the bidirectional flow of information between cells and their local ECM. Examples of the five major classes of cell adhesion receptors include integrins, Ig superfamily, selectins, cadherins, and cell surface proteoglycans.

the major receptors facilitating cell–ECM interactions. Some interesting examples of nonintegrin receptors mediating cellular communication with the ECM include the cell surface proteoglycans (Glypicans and Syndecans) as well as specific receptor tyrosine kinases.

Syndecans are transmembrane heparin sulfate proteoglycan. At least four distinct syndecans have been identified and studies have suggested that syndecans 1, 2, and 4 can bind to a number of ECM molecules. The syndecans are multidomain transmembrane molecules with an extracellular domain containing heparin sulfate GAG chains. It is thought that syndecan interactions with ECM components such as laminin and fibronectin are mediated primarily by interactions with the GAG chains rather than with core protein sequences. In fact, ECM binding specificity can be modulated by the degree of GAG sulfation as well as the length and composition of the disaccharide moieties. Syndecans have a conserved transmembrane domain and a short cytoplasmic domain containing three subdomains termed C1, V, and C2. The cytoplasmic domain has been shown to interact with cytoplasmic proteins such as src, cortactin, PIP2, and PKCα. The capacity of the syndecans to bind to these cytoplasmic proteins is thought to facilitate signal transduction. In this regard, syndecans contribute to the regulation of cellular proliferation and survival. Moreover, syndecans interact with a number of growth factors, cytokines, and protease inhibitors. These unique interactions can facilitate the regulation of protease and cytokine activity in close proximity to the cell surface.

As mentioned above, integrins are the major family of cell adhesion receptors that mediate cellular interactions with the ECM (Table 2). However, several β1 and β2 subunit containing integrins mediate cell–cell interactions by interacting with counter receptors and other binding ligands expressed on adjacent cells. Integrins represent a large family of heterodimeric transmembrane proteins composed of noncovalently associated α and β chains. The α and β chains represent distinct gene products with alternatively spliced forms identified. To date, at least 18 α and 9 β subunits have been described. Distinct combinations of the α and β chains lead to the formation of at least 24 distinct integrins with different ligand and tissues specificities. The functional integrin heterodimer is composed of a ligand-binding globular extracellular domain containing repeated regions with cation binding capacity. In addition, integrins have a transmembrane domain and a short cytoplasmic tail that has the capacity to bind to a wide array of cytosolic proteins known to be crucial in facilitating signal transduction. Studies have suggested that ligand-binding specificity

Tab. 2 Examples of selected integrins and their ECM ligands.

ECM ligand	*Integrin*
Collagens	$\alpha1\beta1$, $\alpha2\beta1$, $\alpha3\beta1$
Laminins	$\alpha1\beta1$, $\alpha2\beta1$, $\alpha6\beta1$, $\alpha7\beta1$, $\alpha6\beta4$, $\alpha v\beta3$, $\alpha3\beta1$
Nidogen	$\alpha3\beta1$, $\alpha v\beta3$
Fibronectin	$\alpha5\beta1$, $\alpha4\beta1$, $\alpha4\beta7$, $\alpha3\beta1$, $\alpha v\beta3$
Vitronectin	$\alpha v\beta1$, $\alpha v\beta3$, $\alpha v\beta5$, $\alpha IIb\beta3$, $\alpha v\beta6$, $\alpha v\beta8$
Thrombospondin	$\alpha3\beta1$, $\alpha v\beta3$, $\alpha IIb\beta3$, $\alpha4\beta1$, $\alpha v\beta1$

and relative affinity is dictated in part by structural conformation, cation binding, and specific contact residues within both the α and β chains. Thus, the affinity and ligand-binding specificity can be regulated at multiple levels, allowing fine-tuning of interactions.

Historically, integrins were thought to function as molecular glue, facilitating physical interactions between cells and the ECM. However, over the last decade, experimental evidence has expanded the repertoire of the molecular ligands and integrin functions (Fig. 4). For example, some of the more well-characterized processes regulated by integrins include cell adhesion, migration, proliferation, cell survival, differentiation, signal transduction, gene expression, and extracellular matrix assembly. Importantly, the multiplicity of functions regulated by integrins is attributable in large part to the vast number of distinct integrin-binding partners. Most of the classical integrin ligands initially identified were ECM proteins, including collagen, laminin, fibronectin, vitronectin, and thrombospondin. Early work on integrin ligands lead to the identification of the tripeptide RGD as an important sequence mediating cell adhesion. However, it has now been confirmed that a wide array of distinct non-RGD-containing proteins can interact with integrin receptors. In some respects, integrins can be thought of as molecular organizational centers on the cell surface since integrins can bind and regulate the activity of a number of different families of molecules (Fig. 4). For

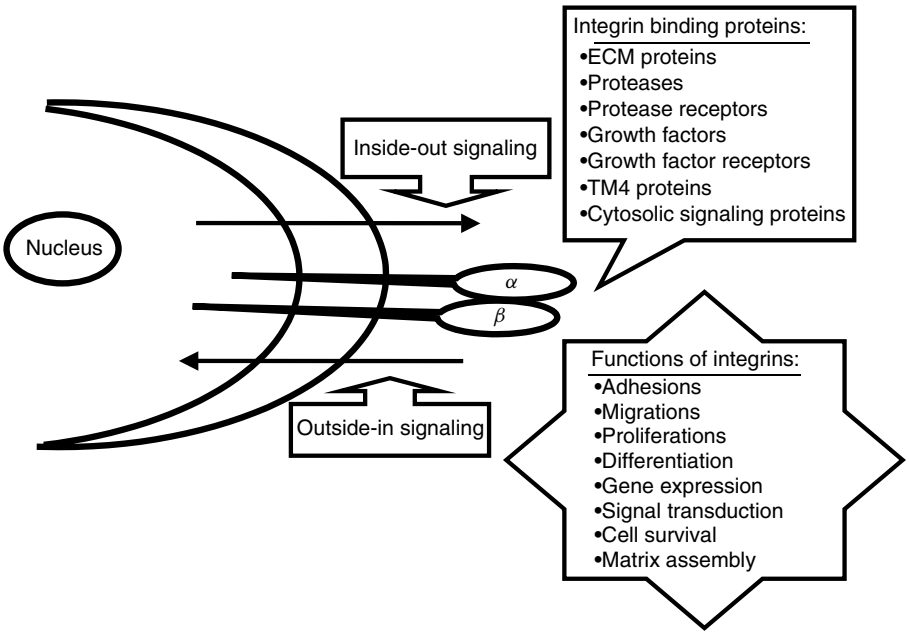

Fig. 4 Integrins: the predominate class of receptors mediating cell–ECM interactions. Integrins represent a family of multifunctional heterodimeric transmembrane receptors, which can bind a wide array of regulatory proteins. Integrin receptors can mediate ''inside-out'' signaling and ''outside-in'' signaling. These distinct signaling cascades can facility bidirectional communication between cells and the local microenvironment.

example, besides ECM proteins, recent studies have indicated that integrins can bind to and associate with such diverse sets of regulatory molecules as proteolytic enzymes, protease receptors, growth factors, growth factor receptors, and TM4 proteins. Thus, it is not surprising that integrins play major roles in regulating the structural assembly, integrity, and remodeling of the ECM. In turn, integrins serve as sensors and molecular responder proteins that facilitate integration and transmission of complex arrays of biochemical and mechanical information from the ECM to the cells. Thus, the capacity of integrin to act as bidirectional signaling receptors, facilitators, sensors, and responders makes them uniquely suited for the job of regulating biological responses to the ECM.

5 Mechanisms of ECM Modification and Remodeling

It is well known that the structural integrity of the BM and interstitial matrix can have a significant impact on cellular behavior. Thus, compositional, biochemical, and structural modification of the ECM can provide mechanisms to alter diverse sets of biological responses. In order to have a significant appreciation of how the ECM influences biological responses, one must first have some insight into the mechanisms by which the ECM is modified and how the unique modifications are recognized and/or interpreted by cells. There is a great diversity of potential mechanisms by which the various components of the ECM can be altered, and thus would be well beyond the scope of our discussion to analyze all of them in detail. Therefore, we have chosen to focus on a few interesting mechanisms as examples of how the ECM can be modulated (Fig. 5).

The molecular composition of distinct ECM compartments can vary substantially, depending on the tissue environment and physiological or pathological events that may be occurring at a particular time. The complex interplay between growth factors, integrins, proteases, and matrix components function cooperatively

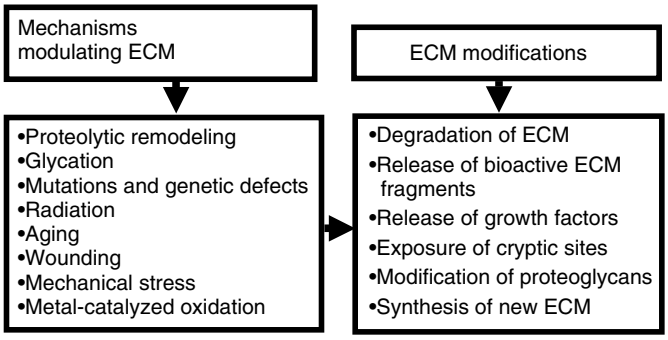

Fig. 5 Mechanisms by which ECM modification can altered cellular behavior. The extracellular microenvironment is not static, but is rather dynamic with numerous changes in structure, integrity, and composition, depending on the cellular repertoire and physiological processes that may be occurring. These important structural and biochemical modifications may lead to altered cellular interactions with the matrix, and thus modify biological responses to the ECM.

to regulate the structure and molecular composition of the ECM. During physiological processes such as embryo development, organogenesis, and wound healing responses, a variety of growth factors and cytokines, including members of the fibroblast growth factor (FGF) and TGFβ families can be released. These growth factors as well as many others can bind cognate receptors on the cell surface, initiating signaling cascades that regulate synthesis of specific ECM components, including collagen, laminin, and fibronectin. Recent studies using mutant embryoid bodies harboring mutations in FGF receptor-2 resulted in altered synthesis of collagen type IV and laminin. Interestingly, this FGF-regulated synthesis of collagen type IV and laminin may be controlled in part by the PI3 kinase and Akt/PKB signaling pathway. Altered ECM synthesis can lead to disruption of BM formation and epithelial differentiation. FGF signaling is also known to play important roles in regulating wound healing and angiogenesis. During these normal physiological responses, elevated levels of FGF have been observed, which, in turn, could lead to significant modification of the preexisting ECM.

A second important example of growth factor regulation of ECM protein synthesis involves TGFβ. It is well known that members of the TFGβ family play important roles in regulation of the expression of collagen and laminin. In fact, differentiation, morphogenesis, and dorsoventral patterning during embryo development are regulated by members of the TGFβ family. Ligation of TGFβ receptors initiate signaling through the SMAD protein family, which can ultimately translocate to the nucleus where they participate in transcriptional regulation by direct DNA-binding events or facilitating formation of transcriptionally active complexes. Thus, developmentally regulated expression patterns and concentration gradient of these growth factors can have a profound impact on the molecular composition of the ECM during physiological development. In turn, the compositional changes occurring during development could provide different binding sites for integrin receptors, other growth factors, matricellular proteins, proteoglycans, and matrix-degrading enzymes. These changes could function to alter signaling pathways, leading to differential regulation of a number of biological responses. It is important to point out that these interconnected events leading to ECM compositional changes can occur not only during normal physiological processes but also play significant roles during pathological events. For example, significant changes in ECM composition occur during inflammatory reaction, pathological angiogenesis, and tumor development. In fact, a reduction in fibronectin expression during tumor development has been observed, while an increase in fibrinogen/fibrin has been documented in association with some tumors. Moreover, studies have shown an increase in vitronectin synthesis in association with glioblastoma, in which the microenvironment is typically characterized with relatively low levels of structural ECM proteins. Finally, another well-documented example of ECM compositional changes involves the matricellular proteins thrombospondin and SPARC. While these proteins are not generally considered structural components, they are upregulated during wounding responses. These matricellular proteins bind components of the ECM and modulate integrin responses such as adhesion, migration, and proliferation.

As has been appreciated for decades, growth factor signaling can influence a

wide array of molecules that modify the ECM, including integrin receptors and proteolytic enzymes. Two major classes of proteolytic enzymes known to modify the structural integrity of the ECM include the serine and matrix metalloproteinase (MMP) families. These classes of enzymes can be regulated at multiple levels, including regulation of transcription, translation, and post translation events, including conformational activation, secretion, glycation, dimerization, and inactivation by inhibitors. Members of the serine and metalloproteinase families are secreted in a latent form and are subsequently activated by a number of mechanisms. Members of the serine protease family such as uPA, tPA, and plasmin can cleave fibronectin, fibrinogen, fibrin, and a number of proteoglycans. The metalloproteinase family, of which at least 24 members have been defined so far, can modify nearly all the components of the ECM, including triple helical collagen, denatured collagen (gelatins), laminin, fibronectin, and proteoglycans. As with most complex biological systems, there exist interconnected regulatory activities between the fibrinolytic cascade and the metalloproteinase system. For example, members of the serine protease family such as plasmin may function to activate latent procollagenase, converting it into an active enzyme. Moreover, certain MMPs such as MMP-9 may degrade serpin protease inhibitors. Interestingly, active proteases from both the fibrinolytic and metalloproteinase systems not only cleave structural components of the ECM but also activate certain growth factors and growth factor receptors, release matrix sequestered molecules, modify proteoglycans, and bind integrins.

Notably, proteolytic enzymes impact the structure and integrity of the ECM in several ways. First, and perhaps the most obvious way, is the degradation of the ECM. Both serine proteases and MMPs degrade components of both the BM and the interstitial matrix. Degradation of major ECM proteins can lead to shifts in molecular composition, alterations in integrin, proteoglycan, and other interaction sites, leading to architectural disorganization. In addition, alterations in ECM proteins can lead to modified integrin signaling, thereby altering gene expression. Second, proteolytic enzymes may not only remove restrictive matrix barriers but, in addition, may also selectively facilitate small conformational changes exposing cryptic regions of ECM proteins that modulate cellular functions. In fact, recent work has lead to the development of Mabs that specifically react with denatured or proteolyzed collagen. Importantly, small alterations in the three-dimensional structure of proteins may impact their susceptibility to biochemical modifications such as glycation, cross-linking or sensitivity to proteolysis. Proteolytic modification of the ECM may also lead to the release of matrix-bound growth factors, protease inhibitors, or other regulatory molecules that are sequestered physically within the matrix. Finally, proteolytic activity could release biologically active fragments of larger ECM proteins that, in turn, might impact cellular responses by binding to the cell surface.

Besides protease-mediated modification of ECM proteins, posttranslational changes of matrix components can also occur. For example, conditions associated with hyperglycemia can lead to the formation of advanced glycation end products or AGEs. The formation of AGEs is associated with nonenzymatic glycation of proteins. Specifically, high glucose levels lead to glucose interacting with free amino groups, forming an unstable shift base. These

functional groups undergo molecular rearrangements, resulting in the formation of Amedori products that ultimately result in the formation of AGEs. The glycation processes have been shown to modify a wide variety of ECM proteins, including distinct forms of collagen, laminin, vitronectin, and fibronectin. Studies have suggested the existence of specific cell surface receptors for these AGEs, which may regulate distinct processes such as chemotaxis, proliferation apoptosis, and angiogenesis. Thus, it is likely that glycation of ECM proteins modulate their functions. In fact, glycation alters their ability to polymerize and associate with other ECM proteins as well as disrupt their capacity to facilitate cell adhesion. In this regard, studies have demonstrated that glycation of the integrin recognition sequence RGD in collagen and fibronectin altered its capacity to promote cell adhesion and migration. In still further studies, glycation of ECM proteins was shown to disrupt processes such matrix assembly, MMP activation, integrin recognition, and signal transduction. Thus, it is clear that glycation of ECM proteins could modify both the structural and functional properties of matrix components.

Interestingly, recent experimental evidence has been provided that both ionizing and nonionizing radiation can cause structural alterations of ECM proteins. For example, it is known that UV irradiation can cause structural cross-linking of proteins such as collagen. Aberrant cross-linking could alter proteolytic and thermal stability, induce changes in protein–protein interactions, and modify integrin recognition. All these structural changes could lead to significant modification of biological responses. In addition, studies have demonstrated that ionizing radiation can cause changes in ECM protein production, thus altering the composition and integrity of the ECM. It was recently shown that a dose of ionizing radiation as small as 20cGy could result in significant loss of the exposure of the HUIV26 cryptic epitope within collagen type IV, both *in vitro* and *in vivo*. While functional expression of the HUIV26 cryptic epitope was reduced by approximately 50%, the exposure of a second cryptic epitope defined by the monoclonal antibody HU177 exhibited little change. These interesting results suggest that small doses of ionizing radiation may have a differential and significant impact on the structure and function of specific ECM proteins. These studies provide a few interesting examples of the potential mechanism by which the ECM can be altered.

6 Modulation of Cellular Behavior by Intact and Structurally Altered ECM Components

The ECM is known to regulate an array of molecular, cellular, and biochemical processes. Crucial to this regulation is the ability of cells to sense and, in turn, respond to their surrounding ECM. Integrin receptors are the major group of molecules that mediate bidirectional communication with the ECM. At least 24 different integrin heterodimers have been characterized with distinct and overlapping binding specificities. By virtue of their ability to interact with an array of cytosolic proteins, integrins are known to transmit signals from outside the cell to the inside. Biochemical changes inside the cell can also be transmitted to the outside by integrins, facilitating bidirectional communication.

Given the diversity of potential integrin signaling events, it would be well beyond the scope of our discussion to analyze them

all in detail. Thus, we will limit our description to a few general concepts crucial for a basic appreciation of integrin signaling and its importance in regulating biological responses to the ECM. Integrin recognition of ECM ligands depends on a variety of molecular parameters, including α and β subunit composition, cation binding, substrate composition, and amino acid sequences. In general, integrin interactions can lead to subunit conformational changes and multimerization. In turn, these conformational changes can lead to the association of a number of cytosolic proteins such as α-actinin and talin with integrin cytoplasmic tails. These initial protein–protein interactions lead to the recruitment of sets of adaptor molecules and kinases, leading to formation of signaling complexes. In addition to direct integrin signaling cascades, integrins can cooperate and cross talk with growth factors and growth factor receptors, thus enhancing the level of complexity and potential mechanisms controlled by integrins.

Some important examples of signaling cascade regulated by integrin–ECM ligation include the Ras-Raf-Mek pathways, the PI3K/AKT pathway, and the JNK pathway. Interestingly, integrin ligation of fibronectin has been shown to regulate apoptosis by initiating specific signaling cascades that modified the expression and activation states of effector molecules such as Bcl-2, Bax, and a number of caspases. Moreover, studies have also shown that integrin–ECM interactions regulate expression of molecules involved in cell cycle control such as cyclins and cyclin-dependent kinases. In addition, studies have documented that integrin signaling controls actin cytoskeleton reorganization and formation of focal adhesions that are involved in the control of cellular migration and invasion. Finally, integrins regulate the expression and activation of matrix altering proteases such as MMPs. Thus, it is clear from the variety of interconnected signaling cascades impacted by integrin binding that the ECM can control a diversity of biological responses.

The diversity of responses to the ECM from a given cell can be altered, depending on the structural integrity of the matrix. For example, it is known that proteolytic degradation of epithelial basement membranes can lead to induction of apoptosis in epithelial cells. MMP-mediated cleavage of interstitial collagen type I promotes melanoma cell survival and suppresses apoptosis by regulating Bcl-2 and Bax expression. Structural changes in ECM proteins can also alter other cellular processes such as migration. For example, studies have shown the MMP-mediated cleavage of laminin-5 resulted in the exposure of a cryptic epitope that promoted breast tumor cell migration. Moreover, MMP-9-dependent cleavage of collagen type IV can expose a cryptic epitope that regulates the migration of retinal endothelial cells. Finally, studies have suggested that MMP-2-mediated cleavage of fibronectin can lead to the exposure of a unique cryptic site that possesses antiadhesive properties.

A wide array of proteolytic fragments of collagen has been shown to modulate distinct biological responses. For example, proteolytic release of the endostatin molecule from the NC domain of collagen type XVIII was shown to inhibit endothelial cell proliferation and migration *in vivo*. Fragments of other NC1 domains from collagen type IV (α1NC1, α2NC1, α3NC1, and α6NC1) have all been shown to modulate cellular responses, including adhesion, migration, invasion, and proliferation. The ability of these collagen fragments to alter cellular events may be due, in part, to their capacity to bind integrin receptors.

Besides specific modules of collagen, proteolytic fragments of other ECM proteins have also exhibited modulatory effects on cells. Structurally altered fibronectin has been shown to modulate matrix assembly by exposing cryptic assembly sites. Fragments of laminin, elastin, SPARC, thrombospondin, and fibrinogen have all been shown to regulate processes such as adhesion, proliferation, motility, and protease production. Thus, cellular interactions with both native as well as structurally altered ECM components play major roles in regulating cellular behavior.

7 Control of Physiological and Pathological Processes by Interactions with the ECM

The rapid growth of gene-targeting techniques has lead to a greater understanding of the functional importance of the ECM in regulating complex sets of biological responses. In fact, greater than 40 mutant and/or ECM knockout mice and 26 integrin null mice have been developed. Studies utilizing these mice have provided unique insight into the interconnected roles of integrins and ECM proteins in the bidirectional flow of information between the ECM and cells. Owing to the number and diversity of studies using these genetic approaches, we have chosen to discuss only a few examples to illustrate the importance of the ECM in regulating biological responses.

A variety of transgenic and mutant mice have been developed that harbor alterations within collagen genes. Interestingly, studies involving mutations or gene knock outs of the $\alpha 1$ chains of collagen types I, II, and III exhibited abnormal blood vessel development, vessel rupture, skin defects, and chondrodysplasia. Mutations have also been introduced into genes encoding collagen types IV, V, VI, VII, IX, X, and XI. The mutant phenotypes of these mice vary from renal failure, skin, skeletal, and cartilage defects to hearing loss. Interestingly, mutations in the $\alpha 1$, $\alpha 2$, and $\alpha 3$ chains of the collagen-binding integrins have exhibited some of the same defects, including skin blistering, renal defects, as well as reduced tumor associated angiogenesis. Thus, alterations in expression of collagen or specific integrins clearly impact crucial biological events.

In addition to collagen, the functional roles of other ECM glycoproteins have been studied using gene-targeting techniques. Mice harboring mutations in the gene coding for fibronectin exhibited abnormal development and defects such as improper somite formation. Similar defects were also observed in mice defective in the fibronectin receptor $\alpha 5\beta 1$, including abnormal vascular and somite development. Mice carrying mutations in specific chains of laminin exhibited a variety of defects, including abnormal BM assembly as well as renal, neuromuscular, central nervous system, and vascular abnormalities. Interestingly, mice defective in laminin-binding integrins ($\alpha 3$, $\alpha 6$, and $\beta 4$ chains) showed similar sets of abnormalities, including renal defects and skin blistering and epithelial malformations. In further studies, mice harboring a mutation in perlecan exhibited defects in heart and brain development as well as chondrodysplasia. Finally, studies with thrombospondin-2 mutant mice suggested an important role for TSP-2 in control of vascular development and collagen matrix assembly.

During early embryonic development, many of the major ECM components are being produced. In fact, studies have shown that by the blastocyst stage, ECM components such as laminin, distinct

isoforms of collagen, fibronectin, and perlecan are already present. Mice lacking the laminin 1γ chain failed to develop proper BM structures and subsequently died at E5.5. This lack of a functional BM was thought to contribute to the failure of endodermal cells to differentiate, ultimately leading to extensive apoptosis and embryo death. During gastrulation, a variety of regulatory molecules and morphogens help establish specific gradients that are critical for pattern formation. Mice deficient in fibronectin exhibit defects in neural tube closure and cardiovascular abnormalities. A critical role for cellular communication with fibronectin is evident since mice lacking $\alpha 5\beta 1$ show similar cardiovascular defects.

Members of the TGF-β family such as BMP-4 are thought to play important roles in early pattern formation through signal transduction cascades mediated by activation of the SMAD family members. Inhibitors of BMP signaling, such as Chordin, contain CR-1 domains. CR-1 domains are thought to facilitate binding of these inhibitors to BMP, thereby blocking receptor binding. Interestingly, these CR-1 domains have been found to be present within a number of proforms of collagen, including procollagen type I II, III, and IV. During the maturation of collagen, the prodomains are enzymatically released. Thus, the CR-1-containing domains may bind to BMP, thereby serving as a regulator of embryonic patterning.

Recent studies have also provided convincing data that invasive and pathological events, such as angiogenesis, tumor growth, and metastasis, are tightly controlled by cellular interaction with the ECM. As with most complex physiological events, angiogenesis or the development of blood vessels from preexisting vessels require the precisely coordinated activities of numerous families of regulatory molecules. Some well-characterized examples of these regulatory proteins include growth factors and their receptors, cell adhesion receptors, proteolytic enzymes, and ECM components. It is interesting to point out that interactions with the ECM can regulate the production, activation, and biodistribution of all these molecular regulator of angiogenesis. In addition, studies have demonstrated that endothelial cells secrete and, in turn, interact with specific components of the ECM such as collagen laminin and fibronectin. In fact, endothelial cell interactions with collagen and laminin were required to initiate morphological reorganization of the endothelial cells into tubelike structures. More recent work has demonstrated that mice harboring mutations in genes coding for specific isoforms of collagen exhibit abnormal vasculature, resulting in embryo death. Moreover, several studies from transgenic mice harboring defects in collagen binding integrins also exhibited defective vascular development. Interestingly, studies have shown that administration of function-blocking antibodies directed to collagen binding integrins such as $\alpha 2\beta 1$ and $\alpha 1\beta 1$ potently blocked angiogenesis *in vivo*. One of the most well-characterized adhesion receptors known to regulate angiogenesis is the $\alpha v\beta 3$ integrin. Importantly, $\alpha v\beta 3$ is highly upregulated on the surface of activated angiogenic blood vessels, while little is expressed on normal quiescent vessels. Antagonists of $\alpha v\beta 3$, including functional blocking antibodies and peptides, have been shown to inhibit angiogenesis in multiple models. In fact, a humanized monoclonal antibody termed *vitaxin* is now being evaluated in human clinical trials for cancer therapy.

The molecular mechanisms by which blocking integrins inhibit angiogenesis are numerous. For example, blocking integrin interactions with ECM components can disrupt cellular adhesion and migration that are known to be required for specific steps during angiogenesis. Besides blocking physical interactions with ECM, disruption of integrin signaling events are also likely to contribute to the inhibitory activity. Integrin ligation of distinct domains within fibronectin differentially regulated the expression of matrix-degrading proteases such as MMPs. In fact, mice lacking either MMP-2 or MMP-9 have been shown to exhibit reduced angiogenesis *in vivo*. Further studies have shown that specific integrins such as $\alpha v\beta 3$ can contribute to the localization of proteolytically active forms of MMP-2 to the surface of invasive cells, thus modulating ECM remodeling. Modulation of protease-mediated ECM remodeling can impact angiogenesis in several ways. In particular, proteolytic release of NC domains of collagen type XVIII (endostatin), collagen type XV (restin), collagen type VIII (vastatin), and various NC domains from collagen type IV (arrestin, tumstatin, and canstatin) have all been shown to inhibit angiogenesis. A wide array of other bioactive ECM fragments have also been shown to either inhibit or induce angiogenesis, including fragments from laminin, fibronectin, fibrinogen, and thrombospondin, to name just a few. Finally, recent studies suggest that proteolytic remodeling of the ECM can expose specific matrix-immobilized cryptic sites. In fact, cellular interactions with the HUIV26 cryptic epitope are mediated by the integrin $\alpha v\beta 3$. A function-blocking monoclonal antibody directed to the HUIV26 cryptic epitope was shown to potently inhibit angiogenesis in several models. Finally, integrin ligations of ECM components are also known to regulate the production of angiogenesis, inducing growth factors such as VEGF and bFGF. Thus, cellular interactions with the ECM can have profound impact on new blood vessel development.

Recent studies have provided evidence that many of the same cellular and molecular processes that regulate angiogenesis also play important roles in tumor growth and metastasis. The concept that modulating ECM interactions with tumor cells can alter their malignant behavior has been extensively evaluated. In fact, blocking tumor cell interactions with the ECM can inhibit tumor cell proliferation, invasion, and metastasis. Thus, while contact independent cell proliferation can be a characteristic of malignant tumor cells, ECM contact is still of great importance.

Interestingly, studies suggest that loss on fibronectin expression correlates with enhanced tumor growth. These studies along with many others provided some of the early evidence that modulation of ECM contacts could influence malignant transformation and the spread of tumor cells to distant sites. For example, a number of $\beta 1$-containing integrins have been shown to play important roles in tumor growth as well as metastasis in multiple murine tumor models. In this regard, transfection of $\alpha 2$ integrin subunit allowing functional expression of $\alpha 2\beta 1$ resulted in enhanced rhabdosarcoma tumor metastasis *in vivo*. Besides $\beta 1$ integrins, a wealth of evidence suggests that many other integrins contribute to tumor growth and progression, including $\alpha 6\beta 4$ and $\alpha v\beta 5$. In studies with human melanoma biopsies, it was shown that nonmalignant skin lesions and radial growth phase melanoma had little, if any, $\alpha v\beta 3$ expression, while vertical growth phase melanoma and metastatic lesions

expressed elevated levels of $\alpha v\beta 3$. Importantly, studies have utilized a number of $\alpha v\beta 3$ antagonists to block tumor growth, including function-blocking Mabs, small peptides, nonpeptidic mimetics, and antisense approaches. The mechanisms by which blocking $\alpha v\beta 3$ function inhibits tumor growth and progression are likely to be many, and perhaps similar to those previously discussed in the context of angiogenesis. These mechanisms might include disruption of physical contact with the ECM, thereby altering traction necessary for tumor cell movement and disruption of signaling cascades. Other potential mechanisms might include altering protease production and growth factor secretion. In fact, it is likely that a combination of many of these mechanisms contribute to the inhibitory activity observed with antagonists of $\alpha v\beta 3$ integrin. Thus, it is clear from the wealth of experimental evidence that tumor cell interactions with the ECM play an important role in regulating many aspects of tumor growth and progression.

8 Conclusions

As can be appreciated from our discussion above, the development of new molecular tools, imaging techniques, as well as gene-targeting procedures have lead to unique insight into the complex structural features of the ECM and how changes within this microenvironment can dramatically alter a plethora of biological events. In fact, over the last decade, investigators have become keenly aware of the great importance of the molecular information contained within the ECM and the critical requirement of transferring this information to cells in order to regulate both physiological as well as pathological processes. Our expanding knowledge of integrin biology has provided important mechanistic understanding of the bidirectional flow of information between cells and their local microenvironment. This insight, in conjunction with the emerging concept that a substantial amount of information is functionally hidden within ECM and only exposed following structural remodeling, has opened up an interesting ''Cryptic'' microenvironment in which to study. This cryptic ECM environment may provide unique molecular insight and provide potential therapeutic targets for the control of genetic defects, angiogenesis, tumor growth, and metastasis. Thus, future studies into the dynamic and fascinating nature of the acellular compartment of multicellular organisms will likely fuel our quest for a more complete understanding of the impact that the ECM has on biological responses.

Keywords

Combinatorial Chemistry
The discipline of high output synthesis of chemical structures in solution, in the solid phase, or by the use of biological expression technologies.

High-throughput Screening
Technologies complementary to combinatorial chemistry that permit the rapid and efficient screening in assays of the biological activities of compounds in an automated manner.

Ligand
A molecule that binds to a receptor to initiate (agonist) or block (antagonist) response. Ligands may be small natural or synthetic molecules (neurotransmitters and their analogs) or large peptides, proteins, or nucleic acids.

Peptidomimetic
A synthetic molecule that mimics the biological properties of peptides and proteins but does not include typical peptide structures.

Receptor
A component of a cell that interacts specifically with (receives) other molecules and, in appropriate combination, initiates (or blocks) biological response. Receptors may be protein, nucleic acid, lipid, or carbohydrate in composition.

Stereoselectivity
The ability of molecules to interact with receptors and other macromolecules in an asymmetric manner such that one structure exhibits preferential interaction or activity. Stereoselectivity is extremely common in biological systems because the building blocks of nature – amino acids, sugars etc. – are chiral.

Structure–Activity Relationships
The definition of the relationship between chemical structure and biological activity. This may be achieved in qualititative terms or, and increasingly, in quantitative terms that involve the determination of the 3D structure of the ligand–receptor complex.

Medicinal chemistry defines one component of a sequence of events in the process of drug discovery and development. The critical steps of lead structure identification and refinement have been, and continue to be, the major contributions of medicinal chemistry to the drug discovery process: medicinal chemistry may be thought of as comprising three stages – a discovery step, an optimization step, and a production step (Fig. 1). Historically, drug development has been associated with biologically active products from natural sources, principally plants, and the development of natural product chemistry. Indeed, some 50% of currently available drugs have their origins, directly or indirectly, in natural products. With the ascendancy of synthetic

organic chemistry, emphasis was increasingly placed on the screening of synthesized molecules in a variety of biological test systems that moved progressively from *in vivo* whole-animal systems to single expressed protein systems and to targets derived from reading of the genome. This approach has acquired increasingly mechanistic underpinnings with the development and quantitation of the receptor concept and the availability of receptor-based assays. The processes of lead structure identification and refinement have become progressively more sophisticated in partnership with developments in molecular and structural biology that have led to the characterization of new potentially drugable targets, the availability of human proteins as research tools with which to study drug–receptor interactions and as biopharmaceuticals, and the availability of three-dimensional structures of human receptors and enzymes with which to perform *in silico* medicinal chemistry. Finally, the new technologies embodied in high-throughput screening and combinatorial chemistry have led to an extraordinary level of biological activity determination: the translation of this productivity into therapeutically available medicines remains, however, a significant problem.

The genomics era, initiated in 1953 with the publication of the Watson and Crick paper on the structure of DNA, has had a major impact not only on biology but also on other scientific disciplines, including chemistry. The basic themes that govern biology – diversity, replication, evolution, and self-organization – are increasingly major components of medicinal chemistry, in the development of combinatorial chemistry, self-replicating molecules, *in vitro* evolution of molecules to biological fitness, and the synthesis of molecules around a template.

The elucidation of the human genome, as well as the genomes of other species including many bacteria, was the second major event of the genomics era. From the perspective of drug discovery, the human genome was anticipated to yield an enormous increase in the number of potential drug targets and thus greatly expedite the availability of new drugs. Together with the technologies of combinatorial chemistry and high-throughput screening, the production line for new drugs was anticipated to be faster and more capacious by several orders of magnitude. However, the number of human genes, approximately 30 000 (but still an uncertain number), is relatively small by comparison with the number of genes in other species, suggesting that our complexity arises not from a simple increase in the number of proteins, but rather from an expansion in the complexity of the signaling and regulatory networks. Thus, the number of potential drug targets is likely to be significantly smaller than was originally anticipated: nonetheless, the anticipated number of 1000 to 2000 potential targets is still significantly larger than the number of current targets, estimated at approximately 120 in all. The issue remains, however, as to how many of these new targets will actually be drugable.

Knowledge of the human genome will also lead to the introduction of *personalized* medicine whereby the drug will be matched more precisely to the patient, thus generating better response, facilitating clinical trial development, and reducing drug withdrawal and related misadventures that are typically due to the reactions with an extremely small percentage of patients, but nonetheless prominent because of the large patient base with many drugs.

1 Background

Active principles from natural sources were the original drugs available to man and still remain a very significant source. References to such products date back thousands of years to the Chinese, Greek and Roman civilizations, and ''natural medicines'' have been used therapeutically since prerecorded times, as part of religious ceremonies, and doubtless also to relieve a life that was ''nasty, short and brutal''. Thus, the acetycholinesterase inhibitor physotigmine, isolated from the Calabar bean was used in the West African tribal ritual of *trial by ordeal*, and various psychoactive substances found in plants have been used for thousands of years. The nature of these principles, which were invariably crude mixtures, was not known and their activity doubtless varied considerably. However, as their chemical constitutions came to be elucidated, they became available as pure materials and also served as leads for synthetic analogs with improved properties. Among the natural products that have served as leads in this manner are the antimalarial quinine, the analgesic morphine, the antihypertensive drug reserpine and the stimulant cocaine (Fig. 2). Introductions in the twentieth century from plant natural sources include many antibiotics such as the penicillins, cephalosporins, and tetracyclines and, more recently, the cholesterol-lowering agent compactin (a lead to the statin family), the immunomodulator cyclosporin, the antimalarial agent artemisinin, and anticancer agents such as paclitaxel, camptothecin, and the bryostatins (Fig. 3). Finally, the discovery of the multiple regulatory and signaling properties of nitric oxide (NO) in neuronal, cardiovascular, immune, and inflammatory responses emphasizes the route to drug discovery through the elucidation of endogenous pathways and structures (Fig. 4).

Despite the early success of plant-based medicinal chemistry, the advent of synthetic organic chemistry resulted in a significant displacement of botanicals as drugs. There is now, however, a significant resurgence of interest in natural products as pharmaceuticals, and due to recent successes, this has led to an increasing

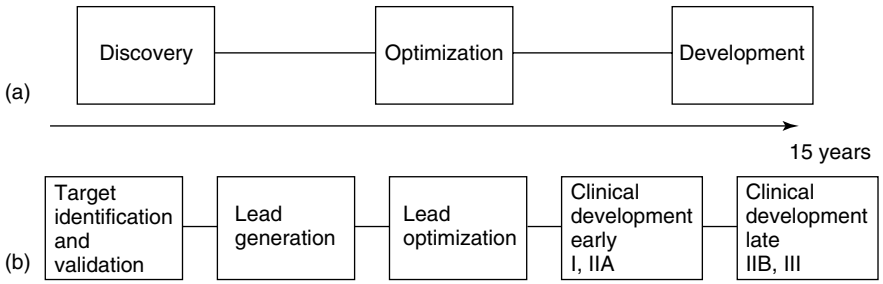

Fig. 1 (a) The drug discovery process may be viewed as composed of three principal stages – *discovery, optimization, development*. (b) The discovery phase may be viewed as composed of five stages: following target identification and validation that may arise from phenotypic or genotypic observations of the two stages of medicinal chemistry – *lead generation and lead optimization* – are initiated. During these two stages, compounds having appropriate pharmacodynamic and pharmacokinetic properties are identified and are subsequently optimized for these properties.

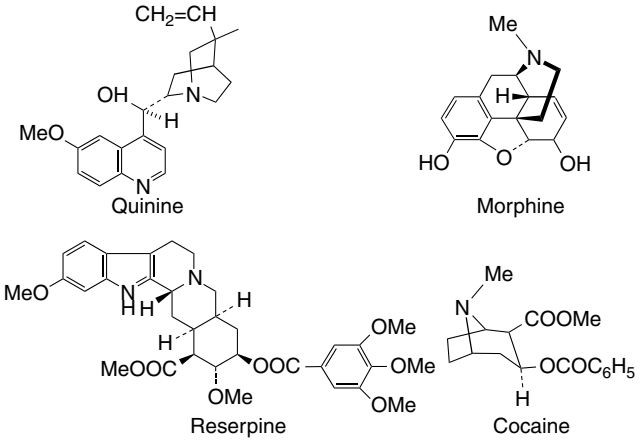

Fig. 2 Examples of potent naturally occurring pharmacologic entities.

understanding of indigenous peoples' healing practices, and to the increasing realization that habitat destruction is causing the loss of potentially valuable drugs and drug leads. For example, it is likely that fertility control has long been practiced by humans through the use of plant-based extracts, including

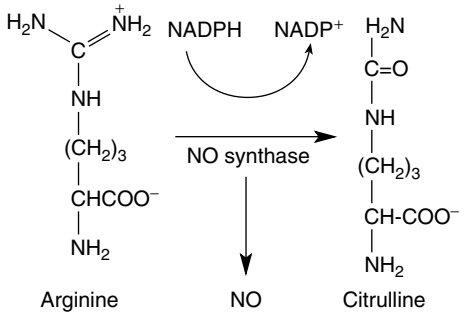

Fig. 4 The nitric oxide (NO synthase) pathway.

one from *Silphion* during the Greek and Roman civilizations:this plant species was apparently harvested to extinction.

2 The Receptor Concept

The concept that drugs act at specific sites, though long recognized, is critical to current processes of drug discovery and to the elucidation of the mechanisms of drug action. Over the past century, the contributions of Paul Ehrlich to immunology and the chemotherapy of protozoan infections, and those of John Newton Langley to drug action in the nervous system are of particular note. Ehrlich viewed receptors as the protoplasmic side chains of cells, and Langley defined a receptor as ''a specially excitable constituent [which] receives the stimulus and, by transmitting it, causes contraction'' [response]. These considerations, together with Emil Fischer's concept of a *lock-and-key* process of small molecule–macromolecule interactions, categorized drug action as specific rather than nonspecific, with defined structure–activity relationships including stereoselectivity, and serving to stimulate or block receptor activity, agonism and antagonism, respectively. The mutual complementarity of the drug molecule and the receptor-binding site provides the underlying basis of structure–activity relationships, the definition and analysis of dose–response relationships and the elucidation, through structural biology techniques, of new ligand structures.

Receptors are classified into several major families, the individual members of which show substantial structural and functional homology. The major classes include the following:

1. The G-protein-coupled receptors: for neurotransmitters (dopamine etc), many polypeptide hormones (substance P, etc.), odorants and light.
2. Ligand-gated ion channels: ion channels with integral receptors for neurotransmitters (acetylcholine, glutamic acid, etc.).
3. Voltage-gated ion channels: ion channels that are activated by changes in cellular electrical potential (Na^+, K^+ and Ca^{2+}).
4. Enzyme-associated receptors: tyrosine kinase, and guanylyl cyclase.
5. Steroid hormone receptors: nuclear transcriptional regulators.

The G-protein-coupled receptor (GPCR) family is one of the largest gene families constituting more than 1% of the human genome, and more than half of all modern drugs have been estimated

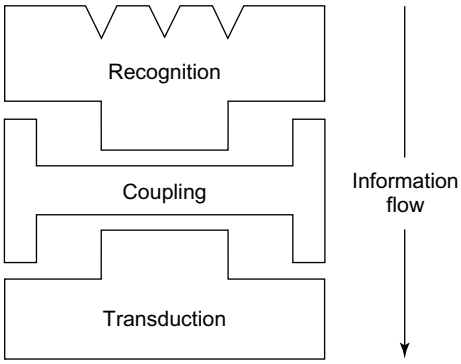

Fig. 5 The receptor, depicted as three discrete entities, as an information generating and processing system.

to be directed at these receptors. This family encompasses receptors for biogenic amines, polypeptide hormones, taste and olfactory stimuli, adhesion ligands and other signaling systems.

Receptors may be viewed as informational machines mediating a vectorial flow of information to the cellular machinery from the ligand, the receptor, or both (Fig. 5). Consistent with this scheme, the majority of receptors are multimeric protein assemblies and their activity may in principle be controlled by drug action at a variety of sites in the complex. Thus, in the G-protein-coupled receptor system depicted in Fig. 6, activity may be regulated by ligand interaction at the receptor-recognition site, at allosteric sites associated with the receptor, through drugs regulating the G-proteins themselves, or through drugs acting on the effectors. The several components of the total receptor complex, and the interfaces between the components, offer multiple opportunities for drug action in addition to the classically defined receptor itself.

Several properties including drug selectivity, affinity, biological response, coupling components, gene sequence, and protein structure determine the overall classification of pharmacological receptors. Thus, in the major family of G-protein-coupled receptors, characterized by a homologous structure with seven transmembrane sequences, there are five principal subclasses of muscarinic receptors (m1–m5) characterized by selective drugs and coupled

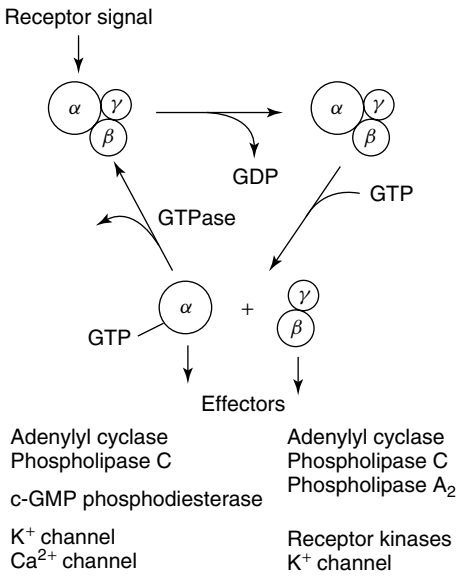

Fig. 6 The organization of heteromeric guanine nucleotide (G) binding proteins as a GTP/GDP exchanger and their coupling to a variety of biological effectors.

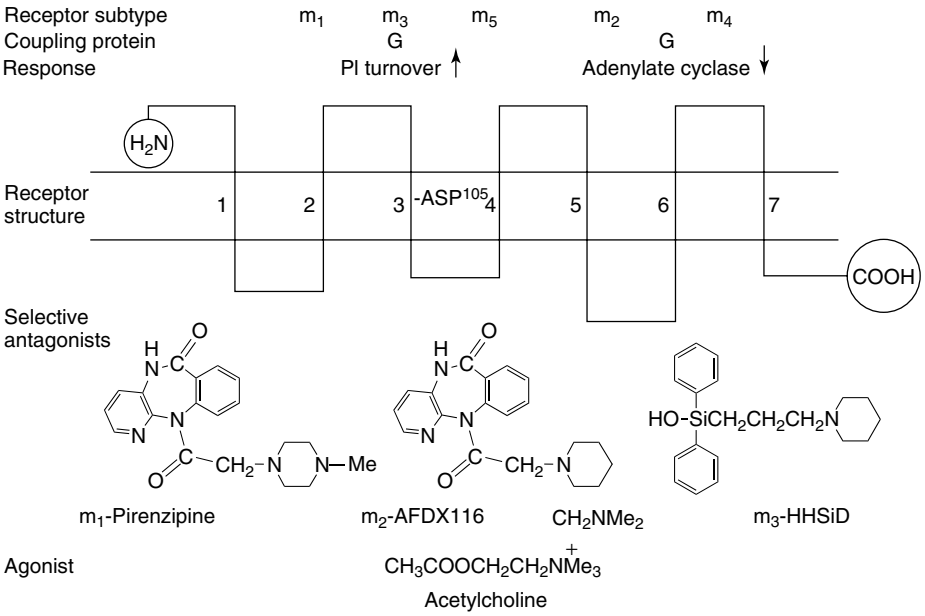

Fig. 7 The muscarinic acetylcholine receptor as a member of the G-protein-coupled family existing as five subtypes – m_1 to m_5 – recognized by selective antagonists and differentially coupled to stimulation of phosphatidylinositol (PI) hydrolysis or inhibition of adenylate cyclase.

differentially to pharmacological effectors (Fig. 7).

The traditional route to the classification, characterization, and eventual isolation of pharmacological receptors has stemmed from the recognition that a specific hormone, neurotransmitter, or drug, produce a defined biological response, that the action of the agent can be mimicked by structurally related compounds with

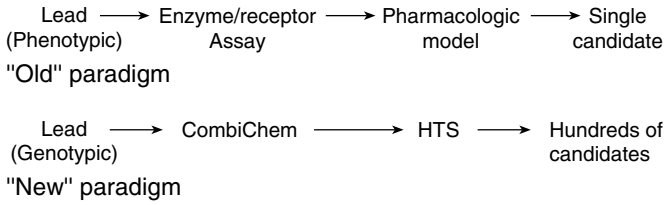

Fig. 8 The ''old'' and ''new'' paradigms of drug discovery. In the old paradigm, a lead target observation, typically a biological (phenotypic) observation such as excess gastric acid secretion or vasoconstriction was used as the basis for an assay into which were fed potential drug candidates typically synthesized ''one molecule at a time'' to generate a single clinical candidate. In the new paradigm, a lead target is derived from a genome database, and high-throughput chemistry and high-throughput screening are applied to generate, in principle, hundreds of clinical candidates.

a definable structure–activity relationship including stereoselectivity and that both agonists and antagonists exist. The actions of a natural product such as morphine led early to the conclusion that endogenous opiods exist for which morphine is a mere surrogate and that there must exist one or more opiod receptors through which the actions of endogenous, naturally occurring, and synthetic opiods occur. From the combined knowledge of receptor structure and the human and other genomes, it is now possible to identify receptors through homology searches in the absence of any knowledge of the endogenous ligand or of the biological responses controlled. The identification of such *orphan* receptors represents a reversal of the classical receptor characterization scheme and provides a further source of potential drug targets (Fig. 8).

3 Chemistry

Traditionally, the medicinal chemistry component of drug discovery has been initiated from a lead structure, either a natural product of plant or animal origin, an endogenous hormone or neurotransmitter, or a synthetic molecule exhibiting some degree of the appropriate biological activity. The lead structure is then optimized to produce the desired potency and selectivity of action and the required pharmacokinetic characteristics. Acquisition of the latter is of particular importance since many agents fail in development because of inadequate solubility, absorption or metabolic properties. This process, essentially a ''one- molecule-at-a-time'' scheme, has achieved many major successes including the development of the β-adrenergic blockers from isoproterenol, the development of angiotensin-converting enzyme (ACE) inhibitors from a peptide teprotide and the development of the angiotensin II receptor antagonists, including losartan, from a weakly active imidazole derivative (Fig. 9). In this process, the biological target, be it blood pressure, acid secretion, tumor growth, anxiety, or depression, has been derived from a biological or phenotypic response.

In the new postgenomic era, it is, however, possible to define targets through analysis of gene structure from the approximately 30 000 genes currently believed to comprise the human genome as well as from the genomes of bacteria, viruses or parasitic species. Although the genomic approach offers, in principle, many new targets, the issue of target validation looms far larger than in the classical process. It is vitally necessary to associate a particular gene with a particular phenotypic expression *and* to demonstrate the relevance of this to the disease process. The techniques of target validation are several and include the analysis of gene and protein expression in normal and diseased tissues. Knockout and conditional knockout animals, the creation of mutant (ethyl-nitrosourea-induced) mice, the use of model organisms including *Drosophila melanogaster* and *Caenorhabditis elegans,* the use of small interfering RNA, and small molecule–based chemical–biological techniques.

With increasing knowledge of the target structure, there is greater emphasis on structure-based drug design whereby X ray, NMR, and computational approaches are employed to provide a physical interpretation of the drug–receptor complex and, in principle, to provide a more rapid and efficient route to drug design. There are still significant limitations

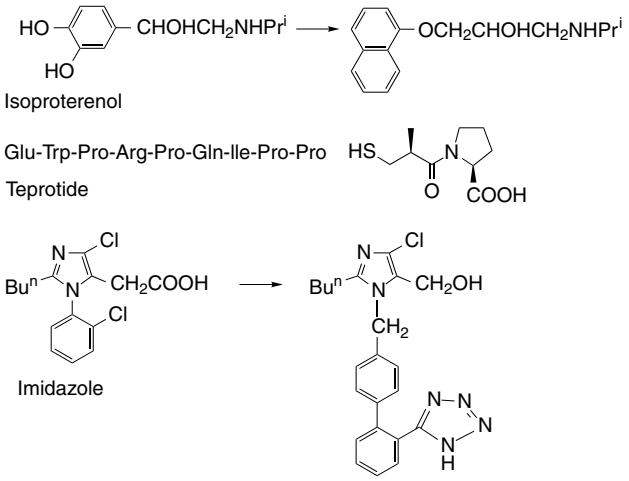

Fig. 9 Examples of lead structures (left) that gave rise to the synthetic antagonists propranolol, captopril, and losartan, active at β-adrenergic receptors, angiotensin-converting enzyme, and angiotensin II receptors, respectively.

to this approach, although it will doubtless continue to assume greater importance. First, the structures of many targets are still unknown and the structures of ligands in solution or in the solid state, although frequently easily accessible, may have no relationship to the structure of the receptor-bound ligand.

At the other extreme of drug discovery has been the development of combinatorial chemistry and high-throughput screening, whereby the ability to synthesize vast chemical libraries and to use automated techniques to screen them against a large number of (typically) genomically derived targets was intended to greatly automate and render more productive the drug discovery process (Fig. 8). This promise remains to be completely fulfilled. However, the synergies obtained by the combined application of combinatorial chemistry and structure-based designs are fueling the new approaches to drug discovery, designed to combine the intelligence of rationality with the efficiency of technology.

3.1 Druglike Molecules

Despite the ability to make chemical libraries of virtually unlimited size, the issue remains that the number of "druglike" molecules is relatively small and that quite limiting chemical and physical properties are necessary to ensure that molecules are both biologically active *and* orally available. A number of approaches have been employed in efforts to quantitate these properties. The best known of these approaches is probably the empirical "rule-of-five" derived from a consideration of over 2000 therapeutically active drugs that indicates a likely problem when a molecule obeys any two of the following conditions:

- Molecular weight >500
- Number of H-bond acceptors >10
- Number of H-bond donors >5
- Calculated logP >5.0.

A number of refinements of this system have been implemented. For example, a

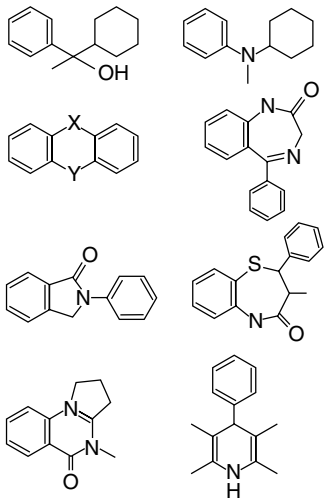

Fig. 10 Examples of *pharmacophoric* structures or building blocks that are commonly found (with appropriate molecular decoration) in pharmacologically active agents.

survey of over 1100 drug candidates at GlaxoSmithKline for which oral bioavailability measurements are available suggests that molecules with reduced flexibility (10 or fewer rotatable bonds) and a polar surface area of less than 140Å^2 (or 12 or fewer H-bond donors or acceptors) are important predictors of good oral bioavailability. These and related approaches have been reasonably successful in predicting ''druglike'' molecules present in large chemical databases such as the Available Chemicals Directory and the Comprehensive Medicinal Chemistry Database.

A second and related issue is that of the chemical structures of active molecules: consistent with the above considerations, these also tend to be relatively limited in terms of potential chemical space and component structures – *pharmacophores* – tend to be conservatively employed. A number of basic pharmacophoric structures or *scaffolds* exist (Fig. 10) onto which are grafted the functional groups that define specific drug families. It is proposed that these structures are those that resist ''hydrophobic collapse'' (the tendency to self-associate to inactive species) through their conformational nonflexibility. Prominent examples of such scaffolds include the 1,4-dihydropyridine and benzodiazepine nuclei, both of which give rise to potent and biologically diverse classes of drugs (Figs. 11 and 12). An interesting example of combinatorial chemistry practiced by Nature, the supreme combinatorial chemist, centers around the venomous snails of the *Conus* genus. These snails produce disulfide-bridged peptide toxins that exhibit both high affinity and selectivity for a variety of neurotransmitter receptors and ion channels. The peptides are synthesized as precursors with a hypervariable C-terminus region, the latter permitting amino acid changes in discrete regions to tailor pharmacological specificity.

3.2 Combinatorial Chemistry and Compound Libraries

Chemical libraries have long been an important proprietary component of the drug discovery process in the search for ''lead'' structures. Such libraries

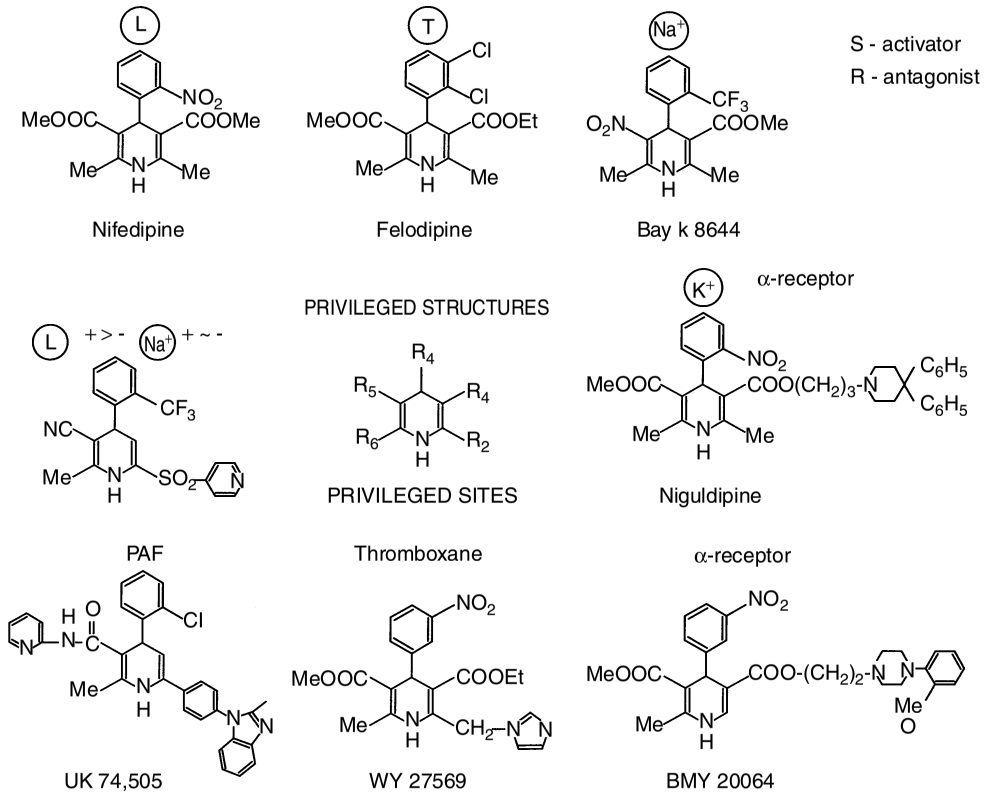

Fig. 11 The 1,4-dihydropyridine nucleus as a *privileged* structure that can be directed at a diverse set of ion channels and pharmacological receptors.

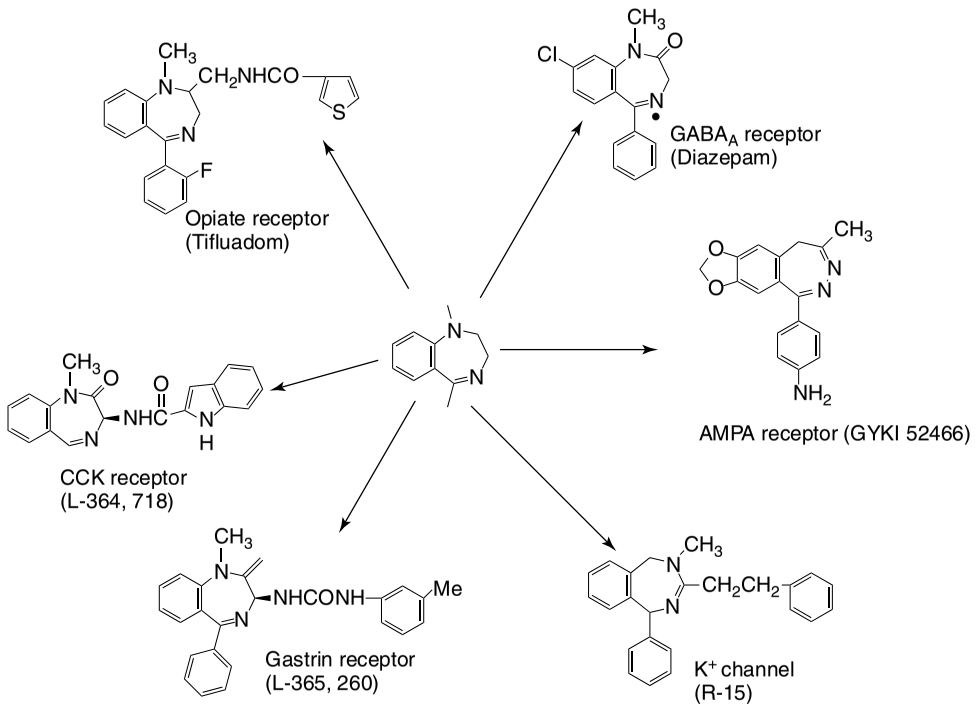

Fig. 12 The 1,4-benodiazepine nucleus as a *privileged* structure capable of interacting at a wide variety of ion channels and pharmacologic receptors.

were typically derived from the traditional ''one-molecule-at-a -time'' approach of drug discovery, and were typically between 1000 and 100 000 molecules in size: these libraries were based to a very significant extent on the previous chemical experience of the company and could vary widely in both molecular diversity and ''drug-likeness''. The technologies of parallel and combinatorial synthesis have dramatically increased library scale. A typical organic chemist can perhaps synthesize 50 to 100 compounds per year. The technique of parallel synthesis in which, with the aid of automation, multiple products can be synthesized in discrete reaction vessels can increase this chemical productivity by a 100-fold factor or more. The combinatorial approach, whether in solution or, more typically, in the solid phase, expands this scale further by performing multiple reactions in a single reaction vessel, creating all possible products from a precursor set of building blocks. A simple calculation illustrates the power of the combinatorial approach. From a basic set of 1000 building blocks, it is possible to construct 1000^5 pentapeptides, or one quadrillion molecules! In general, if the number of available building blocks is a, the number of synthetic steps is x and the same number of building blocks is used per step, then N, the number of individual compounds is given by

$$N = a^{\mathrm{x}} \qquad (1)$$

And if the number of building blocks varies in each step (e, f, g in a three-step reaction), then

$$N = \mathrm{e.f.g} \qquad (2)$$

In principle, one can make more compounds by combinatorial chemistry than there is mass in the universe! Although the original thrust of combinatorial chemistry (coupled with the simultaneous development of high-throughput screening) was designed to produce as many molecules as possible and was a retreat from rational discovery processes, the paucity of success in such large random libraries led to a refocusing of combinatorial thinking to factor in both diversity and druglike properties in the construction of smaller libraries.

The selection and choice of building blocks *and* the linking chemistry are the critical steps in the combinatorial process. For example, the development of peptide and oligonucleotide libraries is quite straightforward since the building blocks and the coupling chemistry are both well known and easily implemented. However, because of the limitations to the use of these structures as drugs, increasing attention is being directed to the use of building blocks that create small-molecule libraries. A second consideration is whether the library is to be used for random screening or for lead development. Increasingly, combinatorial chemistry is used in the generation of ''focused'' libraries that are designed either to cover wide areas of chemical space in as small a collection as possible or to exploit chemical space around a particular structure. Furthermore, the need for such libraries to contain ''druglike'' molecules is increasingly recognized. The choice of natural products as libraries has much to commend it since these molecules, complex as they appear, have evolved and have been ''forged in the crucible of evolution'' to have specific biological functions and to bind to proteins or nucleic acids. A number of such natural product libraries are shown in Fig. 13. In any event, library design and development increasingly includes consideration of those molecular features that provide appropriate pharmacokinetic characteristics.

Fig. 13 Combinatorial libraries based on natural product lead structures.

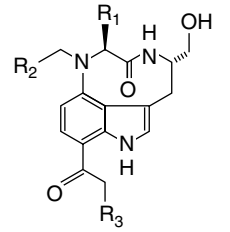
Sarcodictyn analogs



Indolactam V analogs

The solid-phase approach of combinatorial chemistry is generally performed on resin particles or on two-dimensional arrays. An illustration of one such process, the split synthesis technique, is provided in Fig. 14. At each synthetic state, the resin support is pooled and then split: this technique overcomes the different reactivities of individual building blocks and ensures the equimolar distribution of the product, which is critical to the quantitation of the subsequent screening process. At the completion of the synthetic sequence, the compounds are cleaved from the resin support. A variety of techniques can be used to deconvolute the library and to identify the active structure(s). One approach is the encoded library in which a code or identifier tag is added at each stage of the synthetic process (Fig. 15). The library can then be ''read'' from the code sequence that is unique to each member of the library. Varying codes may be employed including sequencable, (nucleotides and peptides), nonsequencable, (fluorophores) or nonmolecular (radiofrequency) codes.

The process of *dynamic combinatorial chemistry* relies on reversible reactions between the building blocks of the system: thus, the composition of the library is under thermodynamic rather than kinetic control (Table 1). This is a critical differentiation from conventional

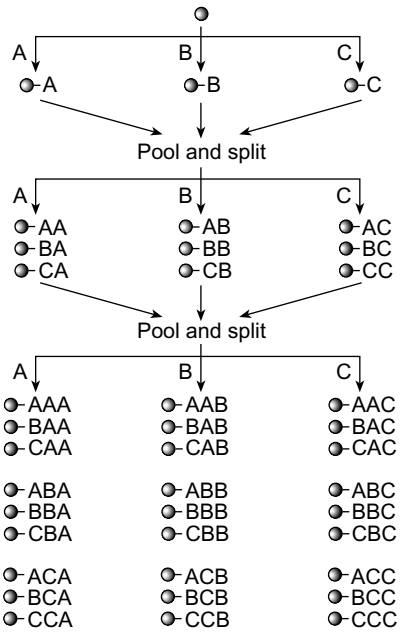


Fig. 14 The split synthesis method for the generation of combinatorial libraries in which each *monomer* is reacted to completion with the solid support and then pooled and split repeatedly to generate the resin-bound library. (From S. Hobbs DeWitt, Pharmaceutical News 1 : 11, 1994.)

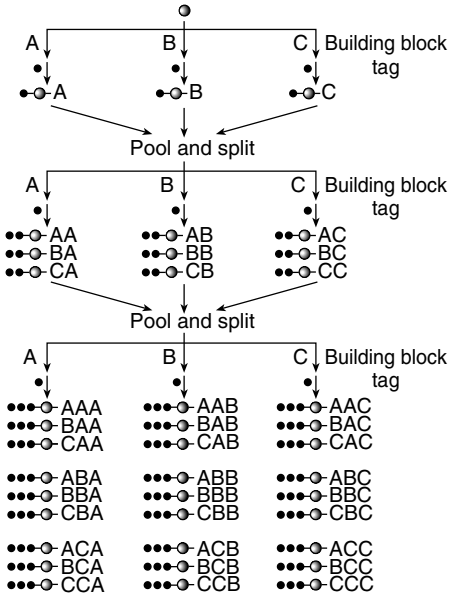

Fig. 15 The encoded combinatorial library in which the addition of each *monomer* is accompanied by a *tag*. The tag sequence that may be chemical or electronic specifically encodes the oligomeric sequence of interest. (From S. Hobbs DeWitt, Pharmaceutical News 1 : 11, 1994.)

Tab. 1 Combinatorial chemistry and dynamic combinatorial chemistry.

Combinatorial libraries	***Dynamic libraries***
Unaffected by recognition	Amplified by recognition
Selected compounds to be made independently	Selected compounds isolable from library
Complex topologies difficult to access	Complex topologies easier to access
Greater chemical access	More limited chemical access
Solubility not important	All members of library must be soluble
Under kinetic control	Under thermodynamic control

combinatorial chemistry because it indicates that the presence of a recognition process specific for one member of the equilibrium will stabilize that member by an equilibrium shift between the reactants and the products (Fig. 16). Accordingly, an *amplification* of yield is obtained. In principle, dynamic combinatorial chemistry offers the heady vision of potent and selective molecules self-assembling in the presence of the biological target and thus automating the entire process of drug discovery. This approach has been applied to a number of systems of biological interest, including the development of inhibitors against neuraminidase using a scaffold reacting with a series of aldehydes to yield a dynamic library of Schiff bases and heminanimals (Fig. 17). In the presence of the target neuraminidase, significant amplification of only the selected components occurred. In a related example, the enzyme acetylcholinesterase was used as a target: a series of acylhydrazides containing a charged amine function (to interact with the enzyme anionic site) and aldehydes yielded a dynamic library from which a compound was isolated with nanomolar inhibitory potency (Fig. 18). In practice, although proof of principle has been obtained in a number of systems, there are limitations, first in the number of suitable reversible reactions available and in both the stability of the target macromolecule under the reaction conditions, and in the presence of undesirable cross reactions between the protein and the chemical reactants.

The process of *target-accelerated synthesis* of active molecules is related to dynamic combinatorial chemistry whereby the coupling of building blocks is accelerated

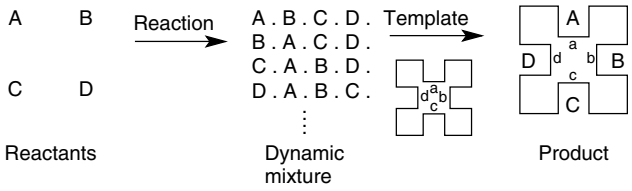

Fig. 16 In the process of dynamic combinatorial chemistry the reactant fragments, A–D, establish an equilibrium of products, one of which is selected by the presence of the template thus driving the overall reaction to select for that specific product.

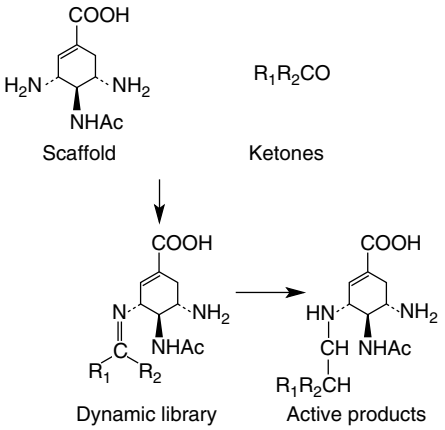
Fig. 17 The use of dynamic combinatorial chemistry to develop a series of inhibitors against neuraminidase. The scaffold entity is reacted with a variety of ketones in the presence of the enzyme neuraminidase to produce by selection the active products.



by assembling them on a target template: since the coupling is covalent, the system is under kinetic rather than under thermodynamic control. An example of target-accelerated synthesis is provided in Fig. 19, which depicts the assembly of an extremely potent (femtomolar KI) acetylcholinesterase inhibitor by 1,3-dipolar cycloaddition chemistry from the depicted starting materials.

Coming full circle back to Nature, combinatorial chemistry can also be achieved in laboratory-based *in vivo* systems through genetic manipulations of bacterial biosynthetic pathways to create new antibiotics and through phage display to generate peptide libraries. Both the polyketide and non-ribosomal classes of antibiotics are synthesized from their carboxylic acid or amino acid precursors, respectively, by large multifunctional polyketide synthases and peptide synthases. The modular construction of these enzymes makes possible their selective modification and thus the biosynthesis of novel products, including active antibiotics. Phage display technologies permit the display of very large peptide libraries that can be used *via* affinity-selection processes to define and target specific recognition sites and can be used to define new potential drug targets in cells and organs via phage targeting.

3.3 Structure-based Approaches to Drug Design

Increasingly, the intuition-based (and highly successful) approach to drug

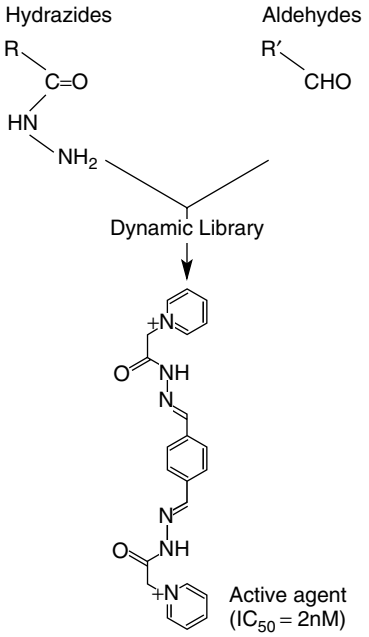


Fig. 18 The use of dynamic combinatorial chemistry to generate a dynamic library that in the presence of the target enzyme, acetylcholinesterase, yielded an active inhibitor with nanomolar affinity.

discovery is assuming a more quantitative character with the addition of structure-based components (Fig. 20). In particular, the understanding of the three-dimensional structure of the target proteins and of their ligand complexes with drugs is proving to be critical for the generation of docking processes to fit new molecules to active sites, *in silico* screening of potential drug structures, the elucidation of mechanisms of drug action, and the development of structure–activity relationships. This approach is frequently referred to as *structure-based drug design*, and with the increasing availability of macromolecular structures via X ray and NMR techniques or homology modeling, it is a rare contemporary drug discovery project that does not have inputs from these design principles. Additionally, the limitations caused by the lack of availability of protein three-dimensional structures are rapidly being resolved by detailed resolution of such membrane proteins as ion channels. With high-throughput protein crystallization processes now in place, it is likely that the next decade will see the majority of protein structures solved, either directly or indirectly, through the use of increasingly sophisticated computational methods.

The antagonists of HIV-1 protease, an enzyme critical to the process of viral assembly and maturation, provides one example of how structure-based design has led to the development of clinically effective and orally active drugs. Homology-based reasoning originally suggested that HIV-1 protease was related mechanistically to the aspartate protease family. This family is characterized by a two-domain active site, with each domain contributing an aspartate residue to the catalytic process. Direct X ray analysis confirmed this, showing the enzyme to be a homodimer with C2 symmetry (Fig. 21). Some symmetry-based antagonists designed from this structure are depicted in Fig. 22.

Most recently, the crystal structure of the angiotensin-converting enzyme complexed with the ACE inhibitor lisinopril has been obtained. ACE inhibitors are important anti-hypertensive agents that play an important role in the control of congestive heart failure. These inhibitors were developed without the knowledge of the structure of the human ACE enzyme but rather were designed on the assumption that the enzyme was mechanistically similar to carboxypeptidase A. There is, however, little three-dimensional similarity, thus indicating a comparatively common

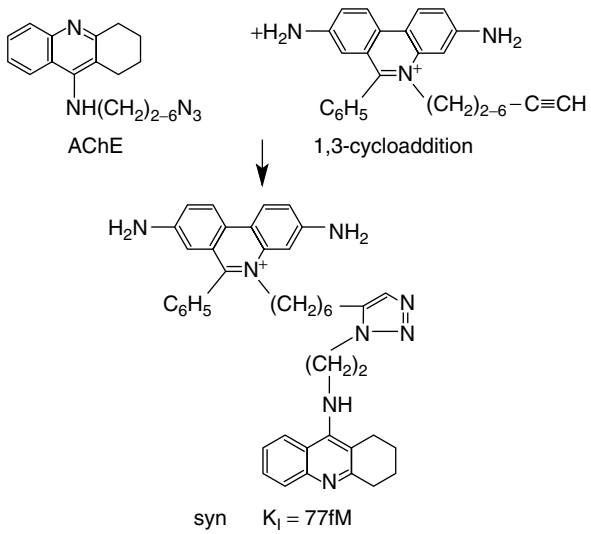

Fig. 19 An example of target-accelerated synthesis of an active molecule. In this example, acetylcholinesterase is the target macromolecule and small-molecule fragments that interact at discrete subsites of the enzyme become linked through 1,3-cycloaddition to yield the active inhibitor with femtomolar potency.

facet of scientific discovery, namely, that significant discoveries can be made on the basis of incorrect assumptions! However, the availability of the ACE structure should facilitate the development of new ACE inhibitors.

The structures of membrane-bound receptors and ion channels have, until recently, not been available at a resolution helpful to the generation of structure-based drug design. Such knowledge is, however, becoming available. In its absence, sequence data, homology modeling, and site-directed mutagenesis have permitted important conclusions to be drawn concerning the residues and topographies that are critical to drug–receptor interactions. The β-adrenergic receptor is a member of the G-protein coupled protein family characterized by the presence of 7 transmembrane helices. Site-directed mutagenesis has revealed the presence of residues critical to both agonist binding and receptor activation. A model for the interaction of the agonist isoproterenol is provided in Fig. 23. The interactions between transmembrane domains V and VI are consistent with observations that the cytoplasmic loop between these domains is critical to the coupling of the receptor and G-protein. Thus, a simple structural model can provide a mechanistic basis for receptor activation and also indicate that molecules that do not make these specific interactions are likely not to function as activators, but rather (as in the case of propranolol) as antagonists. Similar studies with receptors for the polypeptide hormone substance P and its nonpeptide antagonist CP 96 345 reveal that they occupy binding sites that are partially distinct (Fig. 24). Residues in transmembrane

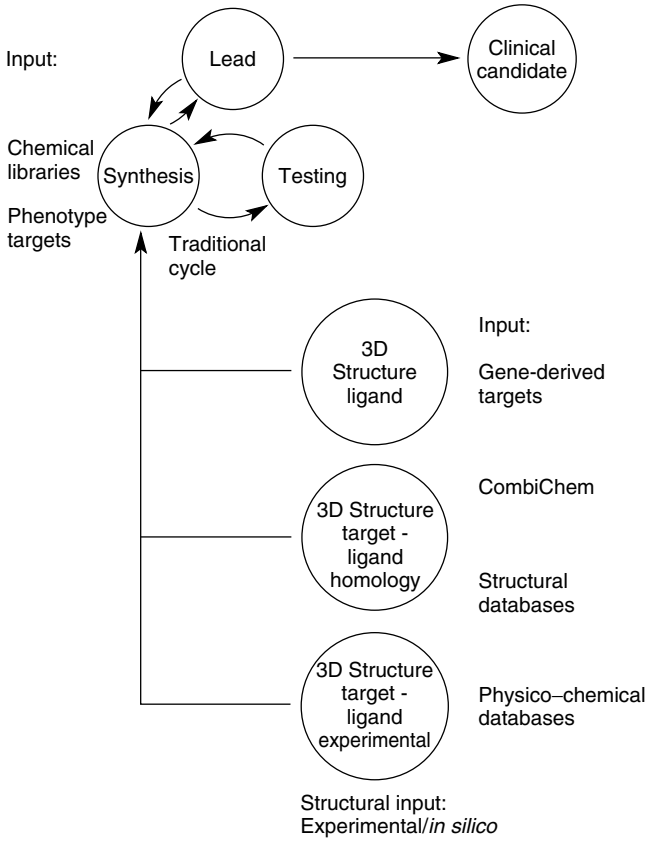

Fig. 20 The incorporation of structure-based drug design into the process of drug discovery. The traditional cycle of discovery (top left) is aided by the components of structure-based design that include inputs from both experimental and *in silico* structural design and from a structural and physicochemical databases.

domains 5 and 6 and the extracellular epitope between these domains are clearly critical for the nonpeptide antagonist, but not for peptide–agonist binding.

Ion channels are an important class of pharmacological receptors and are the loci of action of many drugs and toxins including, tetrodotoxin, pyrethroids, calcium channel antagonists, snake venoms and type II antidiabetic drugs (Fig. 25). The understanding of both channel function and drug action is being greatly facilitated by the availability of three-dimensional structures of several potassium channels. These studies, generally confirmatory of some fifty years of electrophysiological work, have elucidated the nature of the channel pore through which K^+ ions selectively flow, the subunit organization of the channel, the receptor site for quaternary ammonium inhibitors (NEt_4^+), and the nature of the voltage-sensing mechanism (Fig. 26).

These structure-based approaches are increasingly complemented by ''expert'' computer-based algorithms that both

(Reproduced with permission from the American Chemical Society from Greer, J., Erickson, J.W., Baldwin, J.J. and Varney, M.D. (1994) *J. Med. Chem.* **37**, 1035.)

generate *and* screen, on a virtual basis, structures that fit protein-receptor sites. Complemented with algorithms that predict pharmacokinetic characteristics (ADME) true *in silico* drug design is likely to be an important component of actual drug discovery in the coming decade.

3.4 Peptidomimetics

The physiologically important ligands for many receptors and enzymes are peptides,

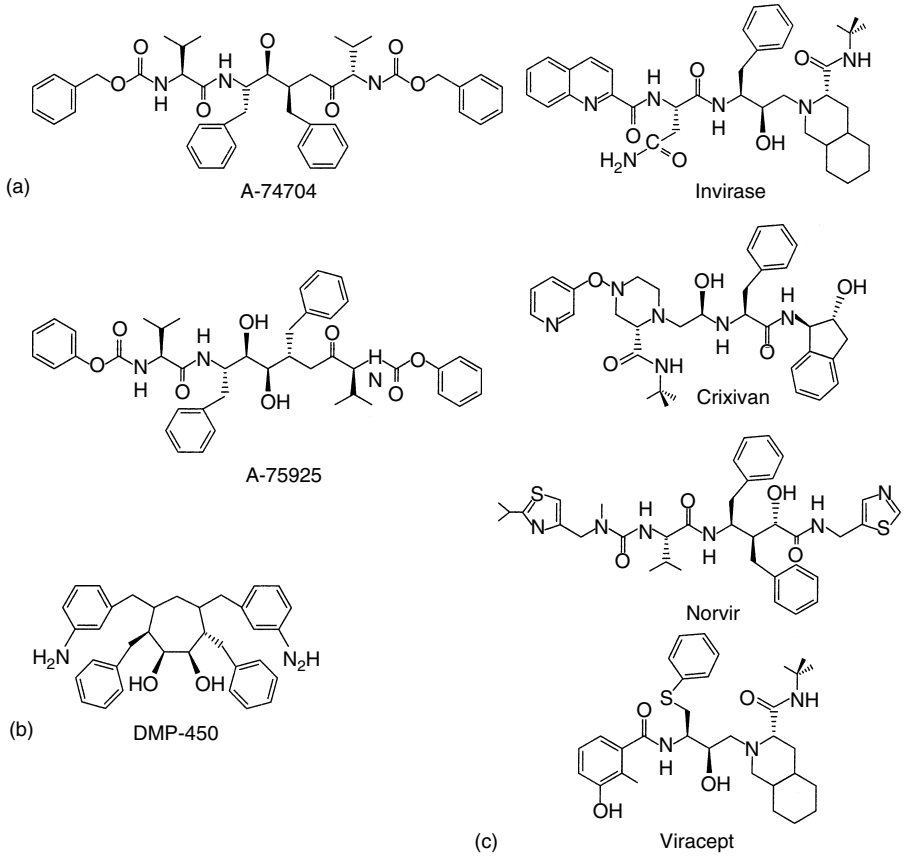

Fig. 22 HIV-1 protease inhibitors.

and the impact of biotechnology on drug discovery has given further emphasis to peptides, both as drugs and as lead structures. However, the disadvantages of short biological half-life, poor bioavailability, and inability to penetrate the central nervous system generally outweigh the potential advantages of potency and selectivity. The search for peptidomimetics – small synthetic molecules that mimic peptide activity – is an increasingly important component of medicinal chemistry. The opiate alkaloids, including morphine, are examples of such peptidomimetics: they

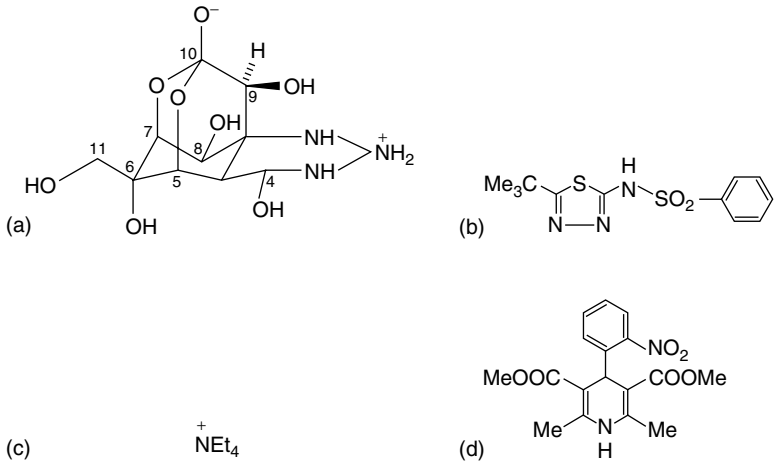

Fig. 25 Drugs that interact with ion channels (a) tetrodotoxin at Na^+ channels, (b) glybuzole at K^+_{ATP} channels, (c) tetraethylammonium at K^+ channels and (d) nifedipine at Ca^{2+} channels.

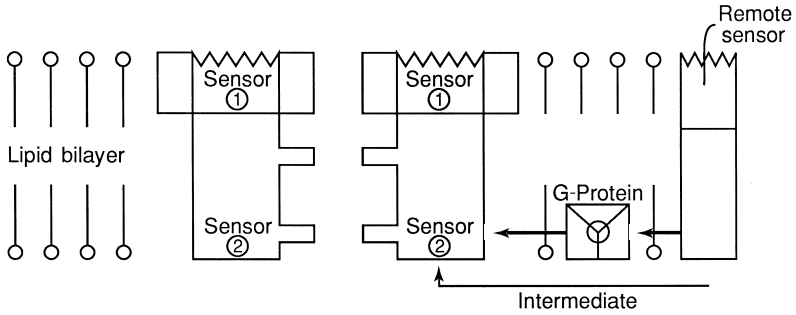

Fig. 26 Schematic representation of an ion channel depicting the pore with "gates" that open and close in response to chemical or physical stimuli, intra- and extracellular sensors associated with the subunits of the ion channel (which is invariably an oligomeric construct) and a remote sensor that is coupled to the channel via cytosolic or membrane signals.

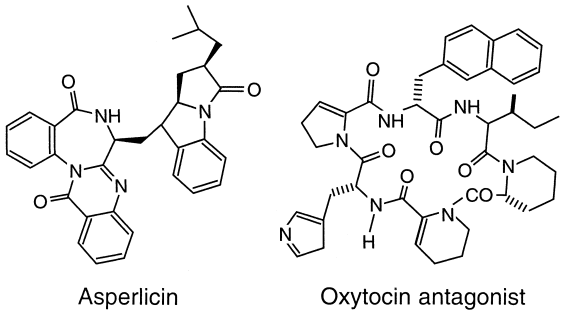
illustrate the principles of peptidomimetic design and demonstrate that peptides and peptidomimetics are frequently structurally quite distinct (Fig. 27). Indeed, the activities of morphine and related compounds were well described long before the endogenous opiod peptides had been discovered!

Peptidomimetics may be considered in three principal categories. *Reaction pathway mimetics* are chemical species that mimic an intermediate, typically a transition state, in an enzyme-catalyzed pathway. *Peptide topographic intermediates* are chemical entities that mimic the topography of non-adjacent peptide regions, and *peptide backbone mimetics* mimic local peptide topography (amide bonds, β-turns etc).

The naturally occurring pepsin inhibitor, pepstatin, contains the amino acid statine.



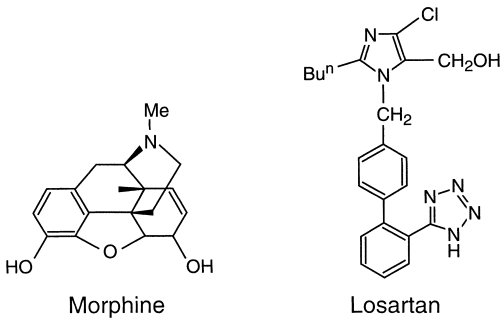


Fig. 27 Examples of nonpeptides that interact at peptide receptors: asperlicin at the cholecystokinin receptor; an oxytocin antagonist interacting at the oxytocin receptor; morphine acting at the opiate receptor; losartan interacting at the angiotensin II receptor.

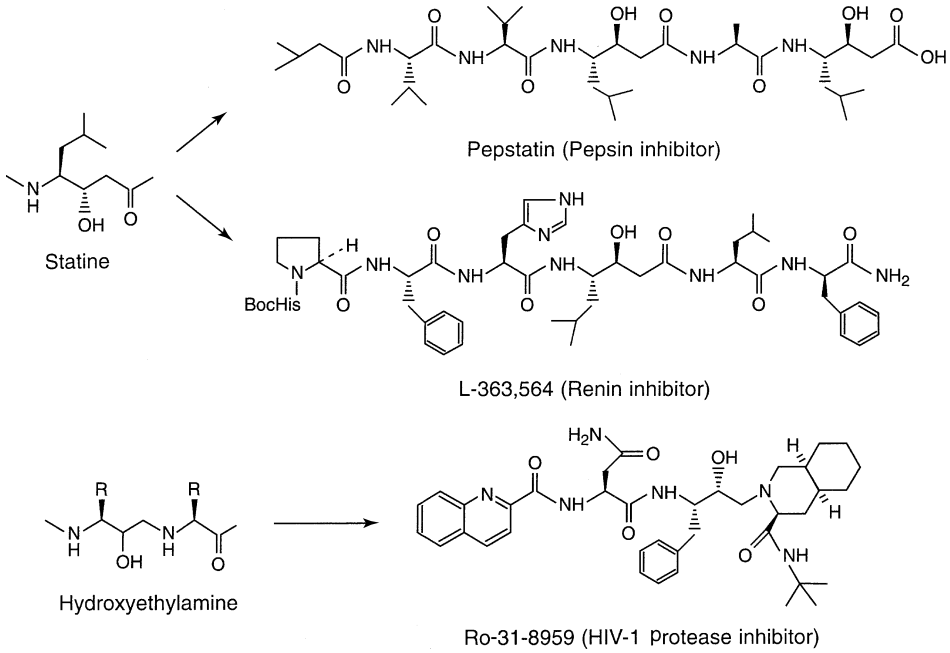

Fig. 28 The statine and hydroxyethylamine structures as peptide mimetics incorporated into the enzyme inhibitors pepstatin, L-363,564, and Ro-31-8959.

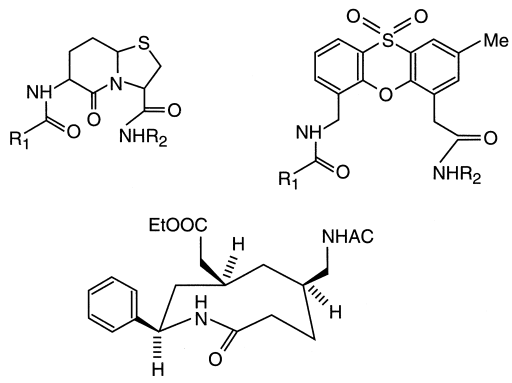

Fig. 29 Examples of peptidomimetic scaffolds.

Statine mimics a dipeptidyl tetrahedral hydrolytic transition state: this mimicking of a transition state likely underlies the ability of pepstatin to inhibit a variety of aspartic proteases, including renin and human immunodeficiency virus (HIV-1). The incorporation of the statin residue into the renin sequence was an important first step in the generation of potential renin inhibitors (Fig. 28). Other replacements serving a similar role in peptidomimetic design include the hydroxyethylene and dihydroxyethylene functionalities, which have generated potent renin inhibitors, and the hydroxyethylamine dipeptide mimetics that are used for generating potent HIV-1 protease inhibitors.

Peptide topographic intermediates are represented by an increasingly large group of compounds, frequently of natural product origin that compete with or mimic peptide actions. Prominent examples include asperlicin, which interacts at cholecystokinin receptors, imidazoles that interact at angiotensin II receptors, and, of course, morphine and its analogs that interact at opiate receptors (Fig. 27).

As part of the process of drug discovery, considerable effort has been devoted to the discovery of compounds that may mimic local protein conformations including β-turns and α-helices. The availability of such structures facilitates the construction of peptidomimetic scaffolds that can be decorated with the appropriate functional groups to generate receptor and enzyme selectivity. Some examples are shown in Fig. 29. The presence of the benzodiazepine nucleus in a variety of receptor-selective ligands is a likely example of such a peptide backbone–mimetic process (Fig. 12).

3.5 Protein–Protein Interactions

The traditional targets of drug design and discovery have been receptors and enzymes, typically viewed as acting independently and communicating through soluble biochemical intermediates, and in which small molecules are the effectors of the function. Increasingly, it is being realized that protein–protein interactions serve as critical mediators of cellular responses. Many receptors, enzymes, and ion channels function as modules composed of communicating subunits, and cells possess anchoring structures that serve to localize and spatially coordinate these protein–protein signaling complexes. Additionally, many receptors such

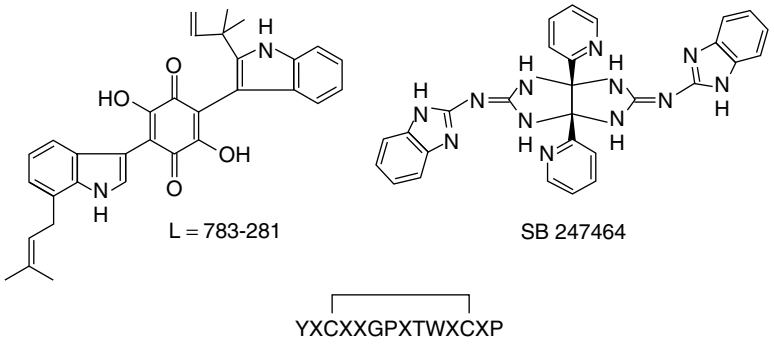

Fig. 30 Small-molecule mimetics of: insulin (L-783-381); erythropoietin (SB 24 7464) and granulocyte-stimulating hormone (cyclic peptide).

as tyrosine kinases that exist as monomers form oligomers under the influence of the activating hormone. The analysis of protein–protein interactions has been greatly facilitated by such technologies as the yeast two-hybrid system. And an increasing number of protein–protein interactions will be identified through the genome project. Hence, protein–protein interactions have become important drug targets. However, the relatively large size of interacting domains in such interactions has raised questions about whether small molecules can effectively interfere with such broad interactions, and whether such molecules would also possess sufficient specificity of action. However, an increasing number of such small molecules are known. For example, Aggrestat and Integrilin mimic the adhesive RGD epitope of fibrinogen interaction with GPIIb/IIIa, and are employed to reduce restenosis in coronary angioplasty. It can be anticipated that advances in our understanding of protein folding and construction will facilitate the design of small-molecule modulators of such interactions.

Of particular interest are studies that have demonstrated that protein hormones can be effectively reduced to small-molecule surrogates that effectively *mimic* the activating properties of the parent hormones. These include small-molecule mimics of insulin, erythropoietin, and granulocyte-stimulating hormone (Fig. 30).

An increasing number of diseases are now known to be associated with protein misfolding, including such degenerative disorders as Alzheimer's and the spongiform encephalopathies. Similarly, in cancer, the p53 gene is frequently mutated giving rise to mutant p53 protein. Small molecules that can restore the wild-type protein conformation may therefore serve as useful therapeutic agents.

3.6 Quantitative Structure–Activity Relationships

The application of quantitative structure–activity relationships rests on the accepted thesis that a mutual structural complementarity exists between the ligand and its binding site and that the biological properties of the ligand are a function of its discrete physicochemical properties, including pKa, electronic configuration, lipophilicity, polar surface area, molar volume, and stereochemistry. An early application of this principle is the

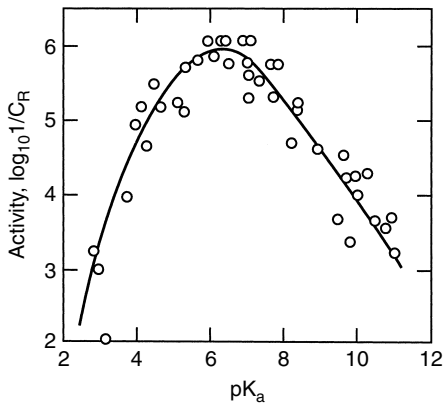

Fig. 31 The relationship between antibacterial activity of sulfonamides (log1/CR) and the pKa of the sulfonamide NH group. (Reproduced with permission from the American Chemical Society from Bell, P.H. and Roblin, R.O., (1942) *J. Amer. Chem. Soc.* **64**, 2905.)

inverse linear relationship observed by Overton and Meyer between water solubility and narcosis. A similarly simple relationship between structure and function was observed in the antibacterial sulfonamides, in which the bell-shaped curve of Fig. 31 indicates that the sulfonamide is active as the anionic species, but permeates the bacterial cell as the neutral molecule.

The definition of QSARs owes much to the pioneering work of Corwin Hansch who, building on the linear free energy relationship expressed in the Hammett equation of physical–organic chemistry, was able to correlate biological activity with hydrophobic, steric, and electronic substituent constants, through multiple linear regression analyses. Thus, for the inhibition of the enzyme acetylcholinesterase by a series of diethyl (substituted phenyl)phosphates:

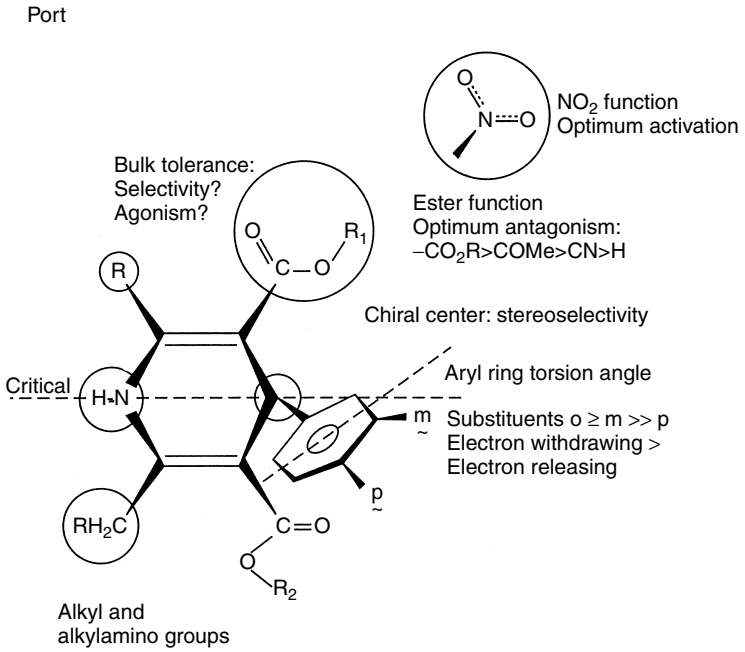
$$\log 1/C_{50} = 5.77\sigma + 2.71 \qquad (3)$$

indicating that the activity in this homologous series of compounds is determined solely by the electronic properties of the substituent in the phenyl ring. More commonly, multiparameter equations are used, giving, for example, the following relationship for the local anesthetic activity of a series of 2-dialkylaminoethylbenzoates:

$$\log 1/C_{50} = 0.58\pi - 1.26\sigma + 0.96 \qquad (4)$$

A more complex relationship is shown in Fig. 32 for a series of substituted 1,4-dihydropyridine calcium channel blockers, selected members of which are widely employed as cardiovascular agents. Activity is dependent upon the hydrophobic, electronic, and steric properties of the aryl substituents.

The QSAR approach in several variations has become a routine component of the practice of medicinal chemistry. There are, however, weaknesses associated with the method: substituent constants must be available and a large and varied experimental data set is necessary to have a statistically powerful analysis. Furthermore, the method defines only the properties of the ligand and usually within a restricted structural set. Thus, the method tends to be retrospective and interpolative rather than predictive and extrapolatable. Nonetheless, its usefulness should not be underestimated, particularly in conjunction with other components of rational drug design.



$$\log 1/C = 0.62\pi + 1.96\sigma_{meta} - 0.44L_{meta} - 3.26B_{1para} - 1.51L_{meta} + 14$$
$$n = 46,\ r = 0.90$$

Fig. 32 The structure–activity relationship for aryl-1,4-dihydropyridines active at the L-type voltage-gated Ca^{2+} channel. The structural formula depicts the general structural features that confer antagonist or activator properties. The equation describes the antagonist activity of a series of 1,4-dihydropyridines with the general formula -2,6-disubstituted-3,5-dicarboalkoxy-4-[substituted phenyl]-1,4-dihydropyridine.

3.7 Stereochemistry

That drug–receptor interactions exhibit stereoselectivity has been well recognized since the time of Pasteur. Indeed, so common is such stereoselectivity that it is generally considered to be an important index of the specificity of such interactions. This stereoselectivity of interaction represents a challenge to our definition of drug actions long recognized chemically, but now increasingly encountered at the clinical and regulatory levels. Clinical significance derives from considerations of the efficacy of a single enantiomer versus a racemate, from considerations of stereoselective metabolism and disposition, and from the impact of the route of administration and interpatient variability of response. Regulatory issues derive from considerations that racemic drugs can represent separate agents in fixed combinations, and development issues derive from considerations of costs, including those for chemical synthesis, and

of pursuing a single enantiomer versus a racemate. (We consider here only optically active isomerism: the same principles apply, however, to geometrical and other isomers. Also, for the sake of brevity, we consider only the case of molecules with a single chiral (stereogenic) center).

Enantiomers can differ both quantitatively and qualitatively in their biological activities. At one extreme, one enantiomer may be totally devoid of activity and at the other extreme both enantiomers may have potent, but distinct, activities. Thus, the following categories of activity are possible:

1. Both the isomers are equally active and there is no stereoselectivity of action. This situation is not common.
2. The isomers differ quantitatively in their activity. Most drugs that occur as stereoisomers fall into this category (in the limiting situation one enantiomer possesses all of the activity).
3. The isomers differ qualitatively in their activity and have discrete biological activity at the same or distinct receptors. Such behavior may translate to agonist and antagonist behavior at the same receptor, subtype selectivity, or activity at distinct receptor classes.
4. The behavior of the isomers in the racemate is different from that of the enantiomers alone.

Examples of racemates in which the enantiomers differ quantitatively in their activity are quite common. They include the positive inotrope dobutamine, the anti-inflammatory ibuprofen, the anticoagulant warfarin, and the local anesthetic bupivacaine. The differences in activity may be large enough to regard one enantiomer as effectively inactive: examples include the β-blocker propranolol in which the *S*-enantiomer is active and the cholinergic agonist bethanchol in which the *S*-enantiomer is also the active entity. Enantiomers that differ qualitatively in their activities include: nicotine where the *R*- and the *S*-enantiomers are substrates and inhibitors respectively of the enzyme *N*-methyltransferase; the 1-methyl-5-phenyl-5-propylbarbituric acid enantiomers in which the S- and R-forms are convulsant and anticonvulsant respectively; propoxyphene in which the enantiomers are analgesic and antitussive; sotalol in which the enantiomers are a β-adrenergic blocker and a K^+ channel blocker; and the enantiomers of Bay K 8644 which are activator and antagonist. Some examples are shown in Fig. 33.

In principle, stereoselectivity of drug action is derived from *both* pharmacodynamic and pharmacokinetic processes and can occur at any or all of the stages depicted in Fig. 34: transport to and from the site of action, storage in depots, interaction with binding proteins, interaction with receptors, metabolic enzymes, and transport in excretory pathways. The Ca^{2+} channel antagonist verapamil is available only as the racemate and is employed as an antianginal, anti-hypertensive and as a selective Class IV antiarrhythmic. The more active *S*-enantiomer is cleared more rapidly through first-pass metabolism. Accordingly, verapamil offers a different clinical profile according to whether it is administered orally or intravenously, being more active in the latter case. Even more subtle distinctions can be made in a comparison of the enantiomers of verapamil on cardiac and vascular smooth muscle: stereoselectivity is very low in the latter and significantly higher in the former (Table 2).

Important differences can exist between the toxicologic or side-effect profiles of enantiomers. For L-DOPA, the levo (available) form is less toxic, vomiting

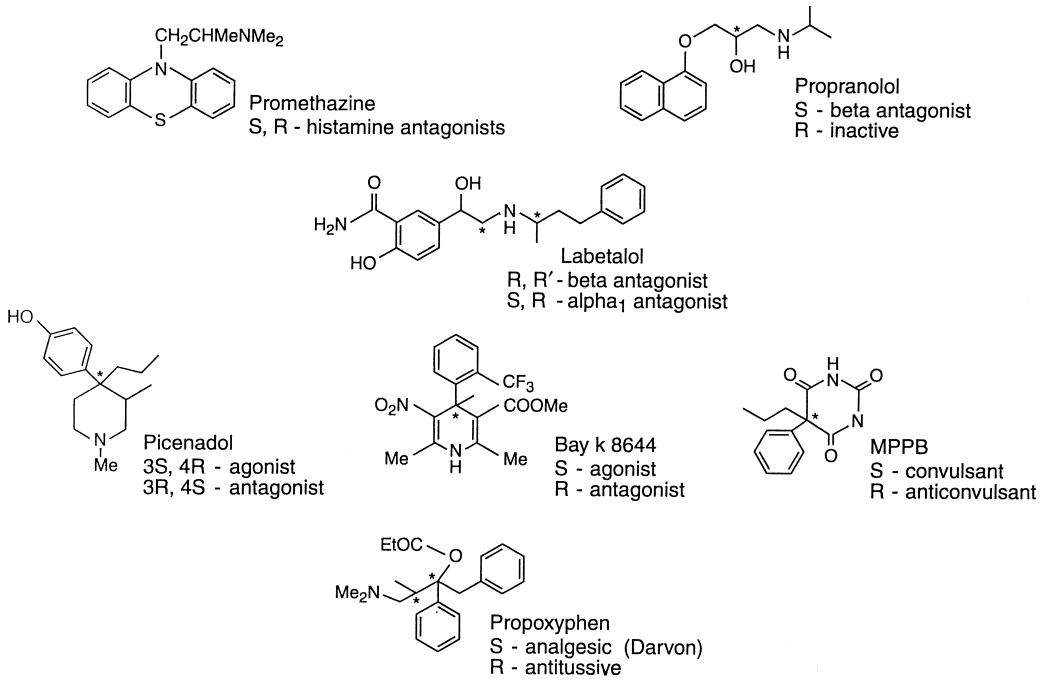


Fig. 33 The stereoselectivity of drug action depicting the quantitative and qualitative differences in biological activity that can exist between enantiomers.

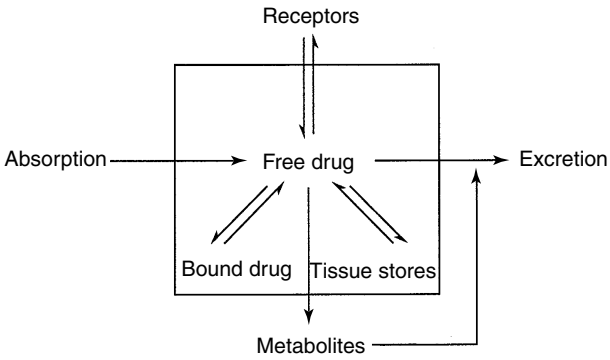

Fig. 34 The observed pharmacological activity of a drug depends upon both pharmacodynamic and pharmacokinetic properties as depicted. Each of the processes depicted has its own structural and stereochemical requirements. These requirements are not necessarily identical at each site and, in fact, may well conflict.

Tab. 2 Stereoselectivity of Verapamil in the cardiovascular system.

	Vasodilation	***Cardiodepression***
	−log EC50 (M)	−log EC50 (M)
Enantiomer		
R(+)−Verapamil	7.31	5.7
S(−)−Verapamil	7.70	7.2

is associated with the D-isomer of levamisole, and the teratogenic effects of thalidomide may be associated with the *S*-enantiomer (however, this has no clinical significance since the enantiomers epimerize very rapidly in solution). Stereoselectivity of general anesthesia has been demonstrated for the volatile agents isoflurane and halothane; although modest, this difference may be of clinical significance and expand the safety margin of these agents.

These considerations are part of an increasing scientific, clinical, and regulatory pressure to evaluate the chirality of drug action at all stages of the drug development process. The use of single enantiomer drugs continues to increase as do conversions of racemates to single enantiomers. Even those in which a racemate may be introduced clinically, this will be done only after the properties of the enantiomers have been thoroughly investigated, and in which it can be demonstrated clinically that there is no disadvantage in the use of a racemate rather than a single enantiomer.

4 The Influence of Molecular Biology

The principles and tools of molecular biology exert an increasing influence on the theory, practice, and application of medicinal chemistry. Molecular biology provides not only the structures of the receptors and targets for drug action, but validates these targets, defines disease states, provides the logic of chemical design, generates the rapid screening protocols, and directly provides drugs and drug candidates. These principles have been elaborated upon previously, but some brief additional comments follow. More

comprehensive discussion will be found elsewhere in this Encyclopedia.

4.1 The Expanded Genetic Code

Our existing genetic code contains 4 nucleotides that specify 64 unique nucleotide triplets that in turn encode the 20 amino acids that are the building blocks for all the proteins in at least this corner of the universe, apart from the rare organism that incorporates selenocysteine and pyrrolysine. The ability to incorporate novel amino acids into proteins has the potential to answer important questions concerning the evolution of life, produce new proteins with novel biological functions and activities, *and* to produce organisms that are biologically unique. Amino acid analogs have been incorporated into proteins by a variety of techniques including posttranslational modification and the use of chemically aminoacylated t-RNA that can be recognized by existing stop codons. However, the generation of autonomous bacteria with an expanded genetic code that can incorporate nonnatural amino acids with efficiency and fidelity represents a major step in harnessing the genetic code for the *in vivo* design and production of novel potential protein therapeutics.

4.2 Genes as Drugs

In principle, gene insertion to replace a defective gene or genes or to enhance expression of a particular gene product provides a permanent curative treatment. The critical issues here for effective gene delivery are the nature of the disease itself, the delivery system and its specificity, the extent and duration of the resultant gene expression, and the safety of the process. Additionally, there are significant ethical issues surrounding gene therapy that are absent with conventional drugs. A number of the potential targets for gene therapy are given in Table 3: clearly, the most plausible targets are monogenic diseases where the disease is due to the presence or misexpression of a single gene.

Gene therapy may be carried out *in vivo* or *in vitro* and the insertion methods are of several kinds. They include adenoviruses and retroviruses that are used as insertional carriers, liposomes to transfer plasmid DNA, and other physical methods including conjugation of the DNA with a protein that targets a specific receptor through which it is internalized.

Although there are in excess of some six hundred protocols, the majority of them being in the field of cancer, clinical success has been limited thus far. In particular,

Tab. 3 Targets and potential targets for gene therapy.

Monogenic diseases
X-Linked severe combined immunodeficiency
ADA deficiency
Cystic fibrosis
Mucopoylaccharidosis
Factor IX deficiency (Hemophilia B)
Familial hypercholesterolemia
Chronic granulomatous disease
Gene types transferred in clinical trials
Cytokines 26%
Antigen 14%
Tumor suppressor 12%
Suicide 8%
Deficiency 8%
Drug resistance 6%
Receptor 4%
Replication inhibitor 3%

the issue of the specificity of the gene insertion process has assumed particular importance, with observations that individuals being treated for X-linked severe combined immunodeficiency syndrome (''bubble boy'' disease) have developed leukemia as a consequence of random insertion of the therapeutic gene near the LM02 gene, a gene linked to leukemia.

4.3 Antisense and Small Interfering RNA

Oligonucleotides bind with great specificity to a variety of nucleic acid and protein targets. Additionally, nucleic acids are particularly well suited for combinatorial chemistry *and* selection processes: oligonucleotides selected from such a process and referred to as *aptamers* can serve both as targeting species (research reagents) to identify small-molecule ligands, and as actual drug species. For example, by using an iterative cycle of RNA library generation, target incubation, removal of non-binding RNA, recovery of bound RNA, and amplification of binding molecules by RT-PCR (Fig. 35), these techniques have led to the identification of small-molecule inhibitors of HIV-1 replication and platelet-derived growth factor binding.

In principle, oligonucleotides with specificity conferred by Watson–Crick pairing will constitute highly specific drugs for defined nucleic acid RNA targets. Thus, an oligonucleotide of some 15–19 bases will have a unique sequence relative to the entire human genome and could, theoretically, offer absolute specificity of interaction. Such oligonucleotides will base-pair to a specific segment of RNA to block translation, block splicing, or facilitate degradation through RNAseH. This is not necessarily realized in practice since the oligonucleotide does not have equal access to all sites on the target RNA. Additionally, oligonucleotides also interact with proteins in a non-antisense manner. Many derivatives of phosphodiester oligonucleotides have been examined, particularly the backbone-modified methylphosphonate, phosphorothioate, and phosphorodithioate analogs (Fig. 36). These modifications serve to enhance chemical stability, reduce non-specific interactions, and enhance cell permeation. However, only one antisense therapeutic, Vitavene$^{(TM)}$, is currently clinically available.

RNA interference is a gene-silencing mechanism originally discovered in lower organisms, but now shown to be widely applicable and to have considerable potential

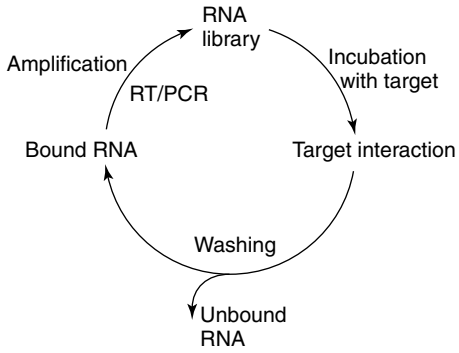

Fig. 35 An iterative cycle whereby RNA molecules that bind to a selected target are identified, amplified and subject to a further round of binding and selection to amplify the desired property.

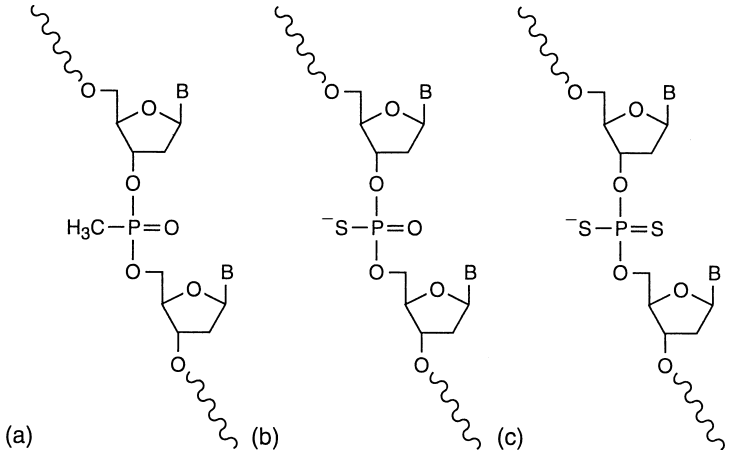

Fig. 36 Backbone-modified oligonucleotides (a) methyphosphonates, (b) phosphorothioates, and (c) phosphorodithioates.

for both target validation and for the generation of actual drugs. In lower organisms, the introduction of double-stranded RNA is followed by enzymatic processing to yield short, 21–22 double-stranded (ds) sRNAs, that guide sequence-specific degradation of the homologous mRNAs. The process is designed to recognize the introduction of RNA from foreign genes during, for example, virus infection, or when transposons and transgenes are randomly inserted. RNA interference (RNAi) can be produced in vertebrates by the introduction of short dsRNA, and serves as a mechanism for specifically silencing gene function. RNAi offers major promise for target validation, being faster than the production of animal knockouts, and the ultimate promise for actual drug delivery. It offers, in principle, significant advantages over antisense technology, since much lower concentrations of the dsRNA are needed, the effects are longer lasting and, of particular significance, siRNA can be produced intracellularly from RNA polymerase III promoters.

Despite the attractiveness of these nucleic acid–based technologies, it cannot be assumed that they are automatically superior to the existing small-molecule techniques. In particular, in protein targets that are part of an oligomeric complex, elimination of one protein could lead to the destruction of that complex and a cascade of effects that would not be produced by the action of a single small-molecule alone acting on the complex.

4.4 Gene-based Drug Targeting and Delivery

Gene-based mechanisms can also be used to confer or to enhance drug sensitivity in an unresponsive cell type. The transfer to cells, for example, of the herpes simplex thymidine kinase(HSV-tk) confers sensitivity to such nucleoside analogs as the antiherpes drug, ganciclovir. Such transfer can be mediated by a retrovirus that incorporates only into actively dividing cells and thus offers particular selectivity for malignant cells. HSV-tk converts the nontoxic ganciclovir into the phosphorylated derivative, which is a chain terminator of DNA synthesis.

5 Summary

Medicinal chemistry, a discipline firmly rooted in synthetic organic chemistry, has increasingly close relationships to structural and computational chemistry, particularly to molecular biology at the discovery interface, to toxicology and pharmacology at the development interface, and to medicine at the clinical interface. The linkage to molecular biology has assumed major significance in the past decade, and chemistry has increasingly been adopting characteristics that are dictated by the basic themes that drive biology – *diversity, replication, evolution,* and *self-organization*. It is entirely conceivable that, as this biological paradigm increasingly permeates science and, in particular, medicinal chemistry, we shall ultimately have Paul Ehrlich's ''magic bullet'' – self-synthesizing, self-replicating, self-evolving, and self-targeting nanomachines that circulate in our body, constantly repairing damage and destroying biological intruders.

Keywords

Clathrin
A large protein complex with a triskelion structure built from three heavy and three light chains, capable of self-associating to form lattices, which coat various vesicles.

Coated Vesicle
60- to 100-nm diameter membrane vesicle that buds from a subcellular compartment, encased in a regular protein coat, which selects vesicle cargo and drives budding. Examples include clathrin-coated and COP-coated vesicles; COP refers to coat protein complex.

Endocytosis
Process by which material is taken up into the cell from the external environment, through incorporation into vesicles, which bud from the plasma membrane.

Membrane Fusion
Merger of lipid bilayer membranes, which is accompanied by the establishment of continuity between the aqueous interiors that are bounded by the originally distinct membranes.

Rab Protein
A member of a large family of small GTPases, which regulate vesicle trafficking, notably through the recruitment of tethering molecules.

Secretory Pathway
A series of compartments that are traversed by material, destined to be, secreted from the cell and which are connected by vesicular transport. Principally comprising the endoplasmic reticulum (ER), ER-Golgi intermediate compartment (ERGIC) Golgi apparatus, and trans-Golgi network (TGN).

SNARE Protein
Member of a conserved family of proteins believed to impart specificity to and catalyze intracellular vesicle fusion.

Tight control of the flux of membrane components through vesicle budding and fusion is essential to cellular organization, giving rise to subcellular compartments with distinct functions. Cargo is generally selected for inclusion into vesicles by specific sorting signals, which are recognized by adaptor proteins, that link to protein components of vesicle coats. The membrane deformation required for vesicle formation is promoted by the coat complex in conjunction with accessory proteins, which may partially insert into the bilayer membrane. Specific targeting of vesicles is initially mediated through ''tethering'' molecules and then cemented through interactions between SNARE proteins, which also catalyze fusion. The essential mechanisms are conserved throughout the cell and from yeast to man.

1
Overview of Cellular Trafficking Pathways

1.1
Maintaining Cellular Compartmentalization

The advent of electron microscopy revealed the complexity of subcellular organization, allowing a first glimpse of a bewildering array of membrane-bounded compartments (Fig. 1). This raised deep questions that are still pertinent to modern day cell biology. How are distinct organelles generated and maintained in the face of a constant flux of material? To what degree is this dependent on spatial organization versus biochemical specification? How should compartments be defined? by morphology, function, or biochemical composition? Much is accomplished through vesicle budding and fusion. In order for this to be so, there must be very specific mechanisms of cargo selection and targeting. Delivery of lysosomal degradative enzymes to the cell nucleus, for example, would court disaster.

1.2
Secretory Pathway

As its name implies, this pathway is taken by molecules destined for cellular secretion. Following translocation of nascent proteins across the ER membrane, proteins must traverse a series of compartments (Fig. 1), including the Golgi stack, where successive posttranslational processing events, such as glycosylation, may take place. The striking stacked cisternae of the Golgi represent a polarized structure, such that the cis-most and trans-most cisternae are highly enriched in distinct enzymes. The number of Golgi stacks may vary dramatically between cell types, but its function is nevertheless conserved.

The trans-Golgi network (TGN) represents the principal sorting station of the secretory pathway. From this compartment, material may be constitutively secreted (e.g. extracellular matrix proteins) or packaged into regulated secretory vesicles (e.g. insulin), which normally undergo

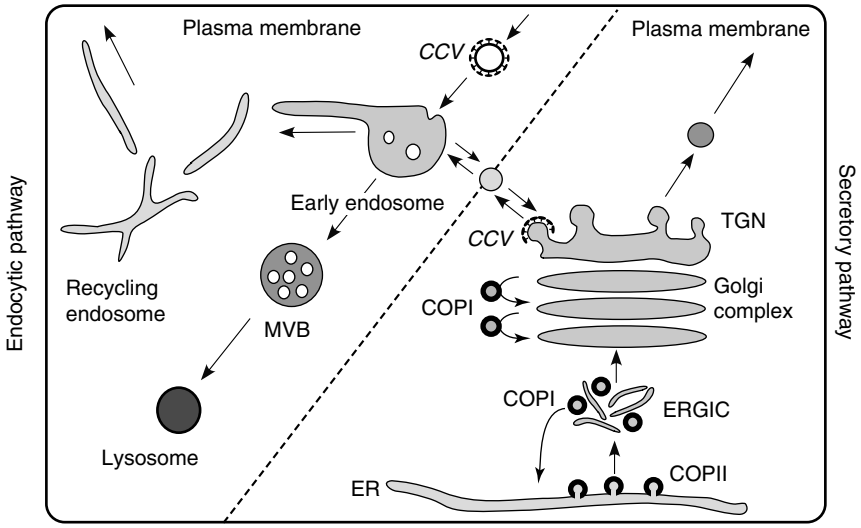

Fig. 1 Schematic diagram of cellular vesicular trafficking pathways in the eukaryotic cell. Newly synthesized proteins translocate into the endoplasmic reticulum (ER) and then progress along the secretory pathway, first by inclusion into COPII coated vesicles, which deliver material to the ER-Golgi intermediate compartment (ERGIC). Tubular elements of the ERGIC may coalesce to form a cis-Golgi cisterna. Anterograde transport toward the plasma membrane, is thought to proceed by maturation of Golgi cisternae, followed by budding of secretory vesicles from the trans-Golgi network (TGN). ER and Golgi resident enzymes are continually retrieved by inclusion into COPI vesicles, which move in a retrograde direction. Material internalized from the plasma membrane may be included in clathrin-coated vesicles (CCVs), which use the AP2 adaptor. The CCVs fuse with the early endosome from where internalized cargo can either be recycled back to the plasma membrane through the tubular recycling endosome or progress toward lysosomes by inclusion in multivesicular bodies (MVBs). Crossover between these two principal highways is mediated by vesicular transport between the TGN and endosomes. Note that other subcellular organelles, such as the nucleus and mitochondria, which do not form part of this endomembrane system are not depicted.

fusion with the plasma membrane (exocytosis) in response to elevated Ca^{2+} levels. Some proteins are diverted at this stage from the secretory pathway toward the endocytic pathway (e.g. lysosomal enzymes).

Progression along the secretory pathway is mediated by vesicular transport. This involves the selection and packaging of cargo into vesicles, which bud off from the limiting membrane and then fuse with specific target membranes. This mechanism can be used to designate forward (anterograde) transport of cargo or retrieval (retrograde transport) of specific components that function earlier in the pathway. Consider transport through the polarized Golgi stacks: according to one view, this is comprised of cisternae, each representing individual stable entities maintained by a delicate balance of retrograde and anterograde vesicular transport. However, it is currently considered more likely that individual cisternae progress through the Golgi complex, gradually undergoing maturation through the selective retrieval of ''earlier'' Golgi markers by incorporation into COP-coated vesicles. This ''cisternal maturation'' model of Golgi transport has

the advantage that it can account for the secretion of large molecules, such as algal scales or collagen, which are too big to be packaged into individual COP-coated vesicles.

1.3 Endocytic Pathway

The best-understood pathway for internalization of material at the plasma membrane is the clathrin-coated vesicle (CCV) pathway, first described by Roth and Porter in mosquito oocytes. However, it has now become clear that several other non-clathrin-mediated pathways operate in parallel. Once internalized, most material is transported to a tubulovesicular compartment, referred to as the *early or sorting endosome*. From this point, endocytosed proteins can enter a pathway for recycling (e.g. transferrin receptor) or be sorted toward the lysosome (e.g. EGF receptor), the major degradative compartment of the cell (Fig. 1). Lysosomal sorting involves the inward budding of cargo containing vesicles from the limiting membrane of sorting endosomes to create multivesicular bodies (MVBs), which then fuse either with late endosomes or directly with lysosomes. The recycling pathway from the early endosome probably involves tubular structures, which break off and direct material through a perinuclear recycling compartment back to the plasma membrane.

1.4 Principle Steps of Vesicular Transport

This article is limited to consideration of membrane trafficking mediated by small vesicles, for which common principles can be extracted. Other trafficking events, for example, generation of tubules for endosomal recycling or inward invagination of vesicles into the endosome lumen will not be considered here. The general mechanism of vesicle transport normally includes the following steps, which are depicted in Fig. 2. A coat assembles on an intracellular membrane through interactions with cargo proteins. Membrane deformation results in vesicular profiles, which must undergo scission to create coated vesicles. Upon uncoating, initial contact with target membranes is made through "tethering" molecules. Finally, the vesicle is committed to fusion through further molecular associations, which may provide the energy to overcome

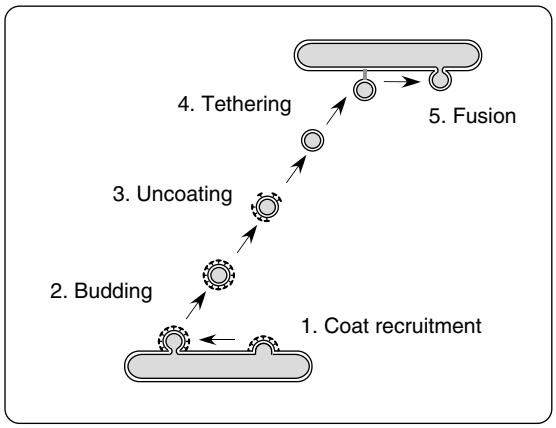

Fig. 2 Basic steps of the vesicle transport cycle (see text for details).

the barriers to membrane fusion, resulting in continuity of both lipid bilayers and lumenal contents.

2 Methodologies

2.1 Subcellular Fractionation

De Duve and colleagues pioneered the use of analytical centrifugation to separate subcellular compartments derived from homogenized tissue. By examining the concomitant separation of specific enzymatic activities, they were able to propose that biochemical pathways were more compartmentalized than previously imagined. Centrifugation techniques have been vital in the purification of various vesicle fractions, including clathrin-coated vesicles, COP-coated vesicles, and synaptic vesicles, thus allowing biochemical analysis of their composition. The introduction of mass spectroscopic techniques for proteomic analysis now allows for in depth profiling of vesicle-associated proteins. A recent study has identified 209 distinct proteins associated with highly purified brain-derived clathrin-coated vesicles.

2.2 Microscopy

The biochemical work of De Duve was brilliantly complemented by the morphological studies of Palade, Claude, Porter, and coworkers, who harnessed the power of electron microscopy to visualize the interior of the cell with a particular focus on the secretory pathway of the pancreatic acinar cell. Jamieson and Palade introduced an *in vitro* ''pulse-chase'' protocol to follow the secretory pathway of nascent proteins. A short incubation of cells with [^{3}H]-leucine selectively labels newly synthesized proteins, which can be visualized by autoradiography and subsequent electron microscopic examination. By varying the time of incubation in the absence of label (chase period) following the labelling ''pulse,'' the progression of proteins through successive secretory compartments could be visualized. Palade frequently observed vesicular profiles in his micrographs and proposed that these may be intermediate vessels for transport between compartments. The introduction of immunocytochemistry and, in particular, the introduction of cryo-electron microscopy by Tokuyasu and Singer paved the way for a quantitative analysis of specific cargo proteins and structural components of vesicles. More recently, the ability to tag proteins with multiple colored fluorescent proteins has made it possible to directly observe protein dynamics through fluorescence microscopy of live cells. Thus, the flux of material in response to a given perturbation can now be followed in real time at the subcellular level.

2.3 Yeast Genetics

A genetic screen in yeast for mutants defective in secretion of specific enzymes identified 23 complementation groups that provided the first set of candidate genes (*sec* genes) for regulation of membrane traffic. The first *sec* gene to be cloned and characterized, *Sec4*, is a ras-like small GTPase belonging to the rab family that acts to target mature secretory vesicles to the plasma membrane. Further screens for mutants defective in vacuolar protein sorting (*vps* genes) or endocytosis (*end* genes) have produced equally informative inventories of genes responsible for specific regulation of membrane traffic.

2.4
Cell-free Assays of Membrane Transport

James Rothman pioneered the development of *in vitro* assays for the reconstitution of membrane trafficking steps. Rothman and coworkers first established a biochemical assay that reconstitutes a specific intracellular fusion event, namely, transport between cis and medial cisternae of the Golgi stack (Fig. 3). They combined wild-type Golgi fractions isolated from CHO cells with Golgi fractions isolated from mutant cells lacking a sugar-modifying (GlcNAc transferase) activity, but containing a model cargo protein, vesicular stomatitis virus glycoprotein (VSVG protein) by virtue of prior infection. This protein is a substrate for GlcNAc, but can only acquire [^{3}H]-radiolabeled GlcNAc by transfer between heterologous Golgi stacks. Rothman and coworkers were able to show that this transfer requires both cytosol and ATP, and thus embarked on a dissection of the cytosolic factors required to support the assay. A major insight derived from this work was that specificity of fusion is principally determined biochemically, rather than by relying on the architecture of the cell interior.

One drawback of this original assay was that it required generation of a vesicular intermediate, and essential factors could therefore operate at the level of vesicle budding, vesicle docking, or vesicle fusion. Subsequent refinements led to the

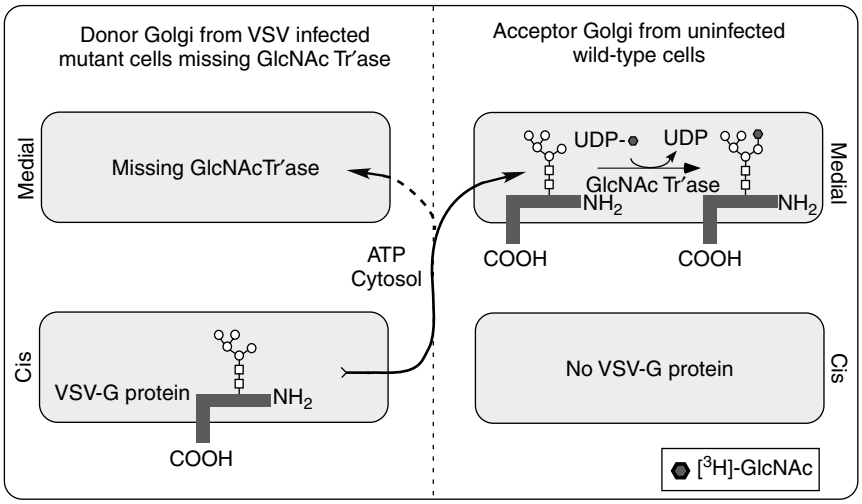

Fig. 3 Schematic diagram of the *in vitro* reconstitution of Golgi transport. The first *in vitro* assay of membrane transport opened the way for a biochemical dissection. Golgi fractions are prepared from two sets of homogenized tissue culture cells, one wild type and the other a mutant cell line lacking the medial-Golgi enzyme GlcNAc transferase, which adds a GlcNAc modification to the carbohydrate chain on secretory proteins. The mutant cells are infected with vesicular stomatitis virus (VSV), for which the spike glycoprotein VSVG provides a model secretory protein. VSVG is accumulated in the cis-Golgi cisternae prior to homogenization. The only way VSVG can acquire [^{3}H] labelled GlcNAc is through contents mixing between the medial-Golgi of wild-type cells and cis-Golgi of mutant cells. Under most conditions, this mixing requires COPI vesicle budding and fusion. This assay was used to fractionate cytosol for factors necessary to obtain efficient radiolabeling of VSVG and led to the identification of NSF, α-SNAP, and characterization of COPI coat proteins.

dissection of individual steps. Assays that reconstitute other transport steps have since been established and developed to the point where both vesicle budding and fusion can be reconstituted with simple model membranes and a minimal set of components. One powerful strategy has been to combine a biochemical approach with yeast genetics, notably in an assay of yeast vacuole fusion. This has allowed the manipulation of membrane proteins in the assay by deletion of specific genes in the parent yeast strains, which then enables the testing of the roles of individual proteins and the topological constraints for their participation in fusion.

3 Evolutionary Conservation of Fundamental Mechanisms

One of the earliest proofs of evolutionary conservation was the isolation of the NEM-sensitive factor (NSF), identified as a critical protein component in cytosol necessary to support mammalian Golgi transport *in vitro*. Rothman and colleagues showed that this protein is functionally equivalent to the *Sec18* gene product of the yeast *Saccharomyces cerevisiae*, which was known to be essential for vesicle-mediated transport from the endoplasmic reticulum to the Golgi apparatus. At one stroke, this not only suggested that NSF might operate at the heart of a fusion mechanism conserved from yeast to mammals but also that it may be required in multiple membrane transport events. Confirmation of this general role of NSF was obtained using *in vitro* assays of endosome fusion and of ER to Golgi transport. This led to the attractive idea that NSF may act as a component of a universal fusion machinery required for every intracellular fusion event. This notion, which is still held to be broadly true (only less direct than initially envisaged), raises the question of how specificity of fusion events is attained.

NSF is recruited to membranes by α-SNAP (Sec17), which in turn binds to a family of proteins called *SNAREs*, that are also conserved from yeast to mammals. SNAREs are believed to be key players in determining specificity of intracellular fusion events and are also the best candidates for catalyzing the membrane fusion event itself. Their intracellular distribution is such that each membrane-bounded compartment is associated with a specific complement of SNAREs that form the basis of a combinatorial code for fusion (see Sect. 7). Recent genome-wide analysis suggests that there are 24 yeast SNAREs with similar numbers in flies and worms. Thirty-five SNAREs have been identified in the human genome, wherein the additional SNAREs predominantly represent tissue-specific isoforms. The current view of NSF function is that it is an ATPase, which configures SNARE proteins into a fusogenic conformation, but is not actively engaged in the fusion step.

This evolutionary conservation has meant that biochemical studies carried out with mammalian cell fractions have dovetailed with yeast genetic studies. The large-scale yeast screens can identify proteins that unerringly have mammalian counterparts, which are identifiable through homology.

4 Signal-mediated versus Bulk Flow Transport

Selective inclusion into transport vesicles is thought to be a major mechanism for establishing discrete compartments. An alternative ''bulk flow'' model posits that

resident proteins are selectively retained, whilst vesicle contents are simply samples of the residual components of the parent organelle. To begin to understand this process, one must be able to compare the contents of the vesicle membrane with the parent membrane. Two approaches have been applied to this problem, quantitative immunoelectron microscopy and biochemical analysis of vesicle fractions. Thus, many studies have established that cargo is actively concentrated in clathrin-coated vesicles budding from the plasma membrane. This may be constitutive, as in the case of the transferrin receptor or regulated, as is the case for epidermal growth factor receptor (EGFR), which requires activation through ligand binding.

This issue has been more contentious when considering anterograde transport through the secretory pathway. Measurements using a glycosylated acyltripeptide as a ''bulk flow'' marker showed a high rate of secretion, suggesting that secretory proteins were nonselectively transported between the ER and the cell surface. However, subsequent analysis indicated that this may reflect a direct efflux pathway, following transport of the glycosylated peptide across the ER membrane to the cytosol.

Immunoelectron microscopical analysis of a SNARE protein (rBet1) has shown that it is enriched approximately sixfold in coat protein complex II (COPII) vesicles that bud from the ER. In contrast, in the same study, two soluble secretory proteins of pancreatic acinar cells, amylase, and chymotrypsinogen were not enriched in these vesicles and were instead concentrated further along the pathway in the tubular structures of the ER-Golgi intermediate compartment (ERGIC), where they are probably enriched by exclusion from COPI vesicles that mediate retrograde transport to the ER. In a separate study utilizing biochemical analysis, Malkus et al. have compared the content of COPII vesicles generated *in vitro* from yeast microsomal fractions with that of the starting material. They clearly show that a soluble protein, glycosylated pro-α-factor, is 20-fold enriched in these vesicles relative to bulk flow markers. A plasma membrane protein, the general amino acid permease (Gap1p), is also enriched in these vesicles by virtue of a di-acidic sorting signal in its COOH-terminal cytosolic domain. Hence, some, but not all, soluble secretory proteins may be selected for entry into COPII vesicles. Others may leave the ER by bulk flow, only to be concentrated in later compartments by selective exclusion from the retrograde COPI vesicle pathway.

Vesicles also contain lipids, which are more than just a permeability barrier to hydrophilic molecules. Brügger et al. have used nanoelectrospray ionization tandem mass spectroscopy to conduct a quantitative analysis of COPI-coated vesicle lipids compared to the parent Golgi composition. Vesicles were found to be de-enriched in both cholesterol and sphingomyelin, indicating that lipids too are subject to selection for inclusion into vesicles.

5
Coated Vesicle Formation

5.1
Coats

Morphological examination of vesicles frequently reveals protein dense coatings on the cytosolic surface. Coat assembly may drive vesicle formation. The first coat to be identified is comprised of hexagonal arrays of clathrin triskelia on the plasma membrane, which must rearrange to a mixture of hexagons and pentagons as the

spherical vesicle forms and buds. Isolated clathrin triskelia can self-assemble into these "basket" structures *in vitro*. The principal sites of clathrin-coated vesicle formation are the plasma membrane and the TGN, from which both are delivered to the early endosome.

The other major class of coated vesicle so far characterized are the COP (coat protein complex) coated vesicles, which mediate retrograde trafficking between the Golgi and the ER, and between Golgi stacks (COPI), and anterograde trafficking from the ER to Golgi (COPII). The COPI coat is formed by Arf-dependent recruitment of "coatamer" (a preassembled heteroheptameric complex) from the cytosol. Arf is a small GTPase that recruits coatamer when it is in a GTP-bound active configuration. Similarly, the Arf family GTPase, Sar1p, choreographs the sequential recruitment of Sec23/24 and Sec13/31 complexes that comprise the COPII coat. Arf family proteins associate with membranes in their GTP-bound state by insertion of a hydrophobic anchor. This is withdrawn upon GTP hydrolysis and Arf dissociation can promote coat disassembly. The COPII component Sec23, is a GTPase-activating protein (GAP) for Sar1, and, so, upon recruitment of the Sec23/24 complex, the vesicles have only a brief opportunity to recruit cargo before coat disassembly begins.

5.2 Adaptors

Adaptor molecules link cargo-selected membrane proteins to the vesicle coat proteins. The first adaptors to be identified were the AP -1 and AP-2 adaptors (adaptor protein), which are highly enriched in TGN- and plasma membrane-derived clathrin-coated vesicles respectively. AP-1 and AP-2 are both heterotetramers of related proteins (AP-1: $\gamma\beta\mu$ and σ, AP-2: $\alpha\beta\mu$ and σ which promote clathrin self-assembly *in vitro*. Phosphoinositide lipids play a role in recruitment of these adaptor complexes; thus AP-1 binds to the TGN-enriched lipid PtdIns4*P*, whereas AP-2 binds to the plasma membrane enriched lipid PtdIns(4,5)P_2. The crystal structure of the AP-2 complex has been solved, revealing potential binding sites for phosphoinositides. Two further adaptor complexes, AP-3 and AP-4 were found by searching sequence databases for homologs of the AP-1 and AP-2 subunits. In distinction to AP-1 and AP-2, these are not enriched in clathrin-coated vesicles and may act independently or in conjunction with an unidentified scaffold to mediate membrane trafficking between the TGN and endosomes. Another class of adapter protein has recently been identified as a family of monomeric proteins called *GGAs* (Golgi-localized γear-containing, ARF-binding proteins), which contain a domain homologous to γ-adaptin. It is clear that they can bind to cargo receptors and clathrin, but, mysteriously, they are not enriched in clathrin-coated vesicles.

5.3 Principles of Cargo Selection

Specific signals mediate sorting of material into clathrin-coated vesicles. These signals may be embedded in the amino acid sequence or otherwise result from either constitutive or regulated posttranslational modification. The first sorting signal to be defined was the NPXY motif in LDL receptor, which resulted from Brown and Goldstein's pioneering studies of familial hypercholesterolemia. Mutation of the

tyrosine residue within this motif leads to failure of LDL receptor endocytosis. Other well-defined signals have since been determined including YXXø where ø is a bulky hydrophobic residue that determines transferrin receptor internalization amongst others. Constitutive posttranslational modification serving as a lumenal sorting signal is exemplified by lysosomal enzymes that are phosphorylated on sugar residues in the cis-Golgi, leading to capture in the TGN by the cation-independent mannose 6-phosphate receptor (ci-M6PR). ci-M6PR receptors are then packaged into AP1 clathrin-coated vesicles destined for the endocytic pathway, through cooperative interactions between GGA proteins and AP-1. A good example of regulated sorting is the ligand-dependent phosphorylation of tyrosine kinase receptors, such as EGFR, which leads to recruitment of accessory factors such as the Cin85/Cbl complex that downregulates receptor from the plasma membrane through incorporation into clathrin-coated vesicles. The number of molecules capable of fulfilling an adaptor function has steadily extended beyond the AP complexes, leading to the notion that there is both redundancy between and specialization of adaptor proteins. Examples include β-arrestin, which couples to seven-transmembrane G-protein-coupled receptors and ARH, which is mutated in patients with autosomal recessive hypercholesterolemia (ARH). ARH patients have a clinical phenotype almost indistinguishable from familial hypercholesterolemia but have normal *LDLR* alleles.

Binding of cargo to Sec24 appears to be the principal means of selection into COPII vesicles budding from the ER. However, the diverse array of cargo molecules utilize more than one binding site, two of which have now been mapped through elegant structural and biochemical studies. Vesicles must also incorporate specific targeting molecules; an interesting study of SNARE incorporation into COPII vesicles has suggested that only fusogenic forms of the SNAREs are selected for transport.

5.4 Induction of Curvature

Producing vesicles requires bending the membrane, which in turn requires energy. A standard bilayer bending modulus is estimated to be around 20 $k_B T$, where k_B is Boltzmann's constant and T the absolute temperature in Kelvin. One view is that the polymerization of the coat on a nascent vesicle induces membrane curvature. Several accessory proteins such as endophilin, amphiphysin, and epsin, implicated in vesicle formation, will tubulate or vesiculate liposomes when incubated *in vitro*. Recently, it has been proposed that BAR (Bin/Amphiphysin/Rvs) domain containing proteins can induce curvature through tight electrostatic association with acidic membranes in the absence of substantial hydrophobic insertion. The structure of the dimeric BAR domain from *Drosophila amphiphysin* is rigid, elongated, and will present a concave face to the membrane, which could accommodate a curved membrane of 11 nm outer radius. This, of course, does not fit well with the radius of coated vesicles (50 – 100 nm). It may be that rather than inducing curvature under physiological conditions, these proteins sense curvature of membranes, as their affinity for preexisting curved membranes will be higher. Bigay et al. have proposed that the BAR domain protein ArfGAP may act as a curvature sensor in COPI vesicle coat disassembly.

An alternative scenario, by which curvature may be induced, is through insertion of hydrophobic groups into one leaflet of the bilayer membrane, which increase the lateral area of this monolayer relative to the other and, consequently, promote curvature. An interesting case is the endocytic regulator epsin, which upon binding the lipid PtdIns(4,5)P_2 undergoes a conformational change that induces an amphipathic α-helix, which can insert into one leaflet of the bilayer. Clathrin-coated vesicle formation at the plasma membrane is promoted by generation of this phosphoinositide, which may also play a role in recruitment of AP-1.

5.5 Vesicle Scission

Budding vesicles can frequently be seen using electron microscopy as omega-shaped profiles protruding from parent membranes. The final step of vesicle scission will require membrane fusion to produce a continuous bilayer. The *shibire* mutation in Drosophila was identified as a temperature-sensitive mutation that caused paralysis through inhibition of synaptic vesicle recycling. It was shown that this defect leads to an accumulation of vesicles at the synaptic membrane that are unable to complete the final scission step. Later, the *shibire* gene was shown to encode a GTPase protein called *dynamin*. Dynamin is able to undergo large-scale oligomerization, wrapping itself around lipid tubules *in vitro*, or around the necks of budding vesicles in *vivo*, to form a helical collar. The pitch of this helix increases as dynamin oligomers undergo highly cooperative GTP hydrolysis. This has led to the ''poppase'' model of vesicle formation, in which this cooperative extension of a dynamin collar is used to provide the force to pop off a budding vesicle.

6 Vesicle Targeting

Once formed, a vesicle must identify its target membrane. The ultimate arbiters of the commitment to vesicle fusion are the SNARE proteins (Sect. 7.3), but prior to their involvement, looser associations are made that allow exploration of the propriety of any union.

6.1 Rab Proteins

One identifier of membrane compartments are the small GTPases of the rab family, of which there are more than 40 members in the human genome. Attention was first focused on this family when the budding yeast protein Sec4 was shown to be a member. Shortly thereafter, work on early endosome fusion in mammalian cells implicated rab5 as a key regulator. It has now been realized that the function of rab proteins is extremely complex. The GTP-bound form of rab5, for example, interacts with upwards of 22 proteins. However, for our purposes, their preeminent role is in their conformation-dependent recruitment of a family of extended coiled-coil proteins or multisubunit complexes, which are believed to act as tethers between interacting membranes (see next section). By recruiting membrane tethers through the GTP-bound form of rab proteins, which possess an intrinsic decay rate due to GTP hydrolysis, it is ensured that the tethering interaction is finite. Thus, if the appropriate downstream interactions, such as SNARE complex formation, are not available, the relationship can be severed before any damage can be done. This provides a form of kinetic proof reading as a potential means of ensuring fidelity.

6.2 Tethering Molecules

Tethering factors are heterogeneous in sequence and structure, but they do fall into distinct classes. A number of extended coiled-coil proteins, which exist as flexible rod-shaped structures of parallel homodimers, have been linked with tethering at the Golgi complex (Golgins) and on endosomes (EEA1, rabaptin 5) and may confine the search for trans-SNARE partners to the tethered membranes. Only a couple of examples for which there is reasonable experimental evidence for this role will be discussed here. EEA1 is proposed to play a role in tethering of endosomes prior to fusion. It is recruited to endosomes through a dual interaction with PtdIns3*P* and GTP-rab5 at its C-terminus, and also has an additional rab5-binding site at its N-terminus. Depletion of EEA1 from the cytosol markedly reduces the efficiency of endosome fusion *in vitro*. The C-terminus of EEA1 also interacts with the SNARE proteins syntaxin 6 and syntaxin 13, both of which have been implicated in endosome fusion.

Attachment of ER-derived vesicles to yeast Golgi *in vitro* was found to require the cytosolic factor Uso1 (a homolog of p115 in mammalian cells) and the small GTPase Ypt1, a member of the Rab family. Removal of Ypt1 from membranes led to a corresponding loss of Uso1, although a direct interaction between the two proteins has so far not been demonstrated. Ypt1 may either bind directly to Uso1 or regulate availability of an alternative receptor-binding site. Interestingly, both factors are also implicated in sorting of cargo at the ER, suggesting a coupling between cargo selection and vesicle tethering.

Another class of tethering molecules exists as multisubunit complexes. Seven large conserved complexes have been proposed to have roles in vesicle tethering at distinct transport steps. These can be divided into two families. One, termed the *quatrefoil complexes*, shares a common N-terminal domain in the majority of complex subunits, which all assemble in multiples of four. They include the Sec6/8 complex (or exocyst), the conserved oligomeric Golgi complex (COG) and the Golgi associated retrograde protein (GARP) complex. The exocyst binds to plasma membrane in budding yeast through recruitment by the Sec4 GTPase, although it is also an effector of other small GTPases. The COG complex localizes to the Golgi complex, although its function is not precisely clear. The GARP complex localizes to the TGN, binds to the SNARE protein Tlg1p, and is implicated in retrograde traffic from endosomes to the Golgi. Other multisubunit complexes, which have rather hazily been ascribed tethering functions, include the TRAPP (transport protein particle) complexes I and II, the class C Vps complex and Dsl1p. Several of these particles contain guanine nucleotide exchange factors (GEFs) that will activate rab GTPases. Thus, subsequent to tethering COPII vesicles to the Golgi, TRAPPI is proposed to activate Ypt1, which, in turn, recruits a second, downstream tether, the coiled-coil protein Uso1p, which has been discussed above.

7 Vesicle Fusion

7.1 Understanding Energy Barriers to Fusion

A condition of membrane fusion is that the membranes must become very closely apposed. Measurement of changes in bilayer spacing in multilamellar vesicles,

as a function of externally applied osmotic or hydrostatic pressure, revealed a surprisingly strong exponentially growing (characteristic decay length of 0.1–0.2 nm) repulsive force between phospholipid bilayers. Under normal circumstances then, bilayers do not spontaneously fuse. Insensitivity of this force to salt concentration and hence membrane electrostatics led to the initial conclusion that the repulsive force is due to hydration of the polar lipid head-groups by water. However, it is now generally believed that other forces also contribute to this repulsion, including steric interactions along with elastic pressures. In addition, an attractive force between closely apposed model membranes has been observed by measurements of adhesion of bilayers supported on mica surfaces in aqueous solutions. This force is believed to arise from exposure of hydrophobic moieties of phospholipids as a result of the stress exerted on bilayer surfaces that approach within about 1 nm.

7.2 Membrane Destabilization

A theoretical analysis of interactions between apposed membranes proposed that out-of-plane thermal fluctuations of the bilayers lead to the formation of close (less than 0.5 nm) contact between the membranes within a small area (approximately 10 nm^2). According to this theory, increasing hydration repulsion between apposed polar heads of lipid molecules in this area causes the rupture of interacting monolayers. This rupture results in monolayer fusion of the membranes, that is, in the formation of a bridge connecting the monolayers, which is usually named the ''stalk'' or hemifusion intermediate that can further evolve to form a hemifusion diaphragm, which then ruptures leading to full fusion.

7.3 SNARE Proteins

The ''SNARE hypothesis'' was proposed in 1993 by Rothman and co-workers to explain the Specificity of intracellular fusion events. It proposes that the core of the fusion machinery is comprised of SNARE proteins that are localized to specific subcellular compartments. Only cognate SNAREs on partner membranes can form a complex that promotes fusion. Following vesicle tethering, partner membranes have the opportunity to form trans-SNARE complexes. The first SNARE complex to be characterized was the one that specifies fusion of synaptic vesicles with the plasma membrane. This interaction, which is believed to be characteristic of all SNARE complexes, involves the formation of a parallel four-helix bundle, termed a ''*SNAREpin*,'' in which one helix is contributed by the vesicle-associated SNARE (v-SNARE) synaptobrevin, whilst the other three are contributed by SNAREs on the target membrane (t-SNAREs). In this case, two of the t-SNARE helices are provided by SNAP-25 and one by syntaxin 1. Sequence analysis has shown that all SNAREs probably derive from a single ancestral gene that has been duplicated in the case of SNAP-25.

SNARE complexes do not simply lock vesicles into a closely associated state; they also drive membrane fusion. Substitution of the transmembrane domains of syntaxin and synaptobrevin with lipid anchors allows the docking interaction of vesicles to proceed, but fusion is no longer observed. The resolution of the SNARE complex structure immediately suggested an attractive mechanism by which fusion is promoted that has been termed

the zipper model. In this model, the assembly of the parallel four-helix bundle occurs initially at the N-termini of the helices and zips up toward the membrane anchors, consequently pulling the partner membranes into close apposition. The SNAREs themselves must tilt toward the membrane during this process, and it is attractive to speculate that this is coupled to deformation of the membrane through the transmembrane anchor (Fig. 4). Insertion of a flexible linker between the transmembrane domain and the coiled-coil domain reduces SNARE-dependent fusion efficiency systematically with increasing length of the linker. Note that after fusion, a SNARE complex will persist, but now in a cis configuration until it is disassembled by the action of NSF, which utilizes ATP hydrolysis.

Evidence that SNAREs participate in a late stage of physiological fusion reactions has been provided by an assay of regulated secretion of dense core vesicles in PC12 cells. In this system, the assembly of the SNARE complex occurred after the rise in Ca^{2+}, and could not be experimentally dissociated from the fusion process. In adrenal chromaffin cells, an antibody that inhibits SNARE assembly also reduces the initial fast component of exocytosis, indicating that even the vesicles poised for the quickest release require the SNARE assembly step.

A finding that the three synaptic SNAREs, when reconstituted into model liposomes and distributed according to cellular physiology, could promote liposome fusion led to a highly influential proposal that the SNAREpin complex represented the minimal fusion machinery. McNew et al. further developed this form of assay by taking advantage of the functional identification of yeast SNARE complexes associated with three specific transport steps, namely fusion of ER-derived transport vesicles with the Golgi, homotypic vacuole fusion, and fusion

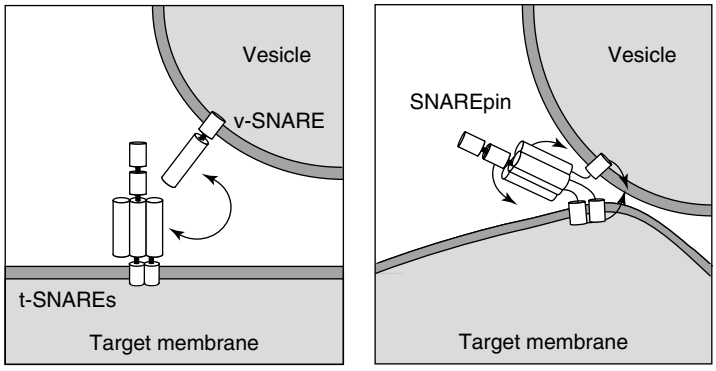

Fig. 4 Model for membrane deformation and fusion mediated by SNARE proteins. (a) The four helical sections of a SNARE complex in a prefusion state are arranged in a 3 : 1 distribution between partner membranes. (b) Progressive zipping of the four helical sections of SNARE proteins leads to the assembly of a tight parallel four-helix bundle (SNAREpin). This process forces membranes into close membrane apposition and will generate stresses at the membrane that are coupled to imposed bending of the participating proteins (indicated by arrows).

of secretory vesicles with the plasma membrane. They tested the fusion activity of liposomes bearing the set of t-SNAREs associated with each of these three steps with liposomes bearing any one of 11 actual or potential v-SNAREs in the yeast genome. The *in vitro* system recapitulated the cellular specificity to a remarkable degree, testifying to the high level of discrimination encoded within the SNARE complex.

These experiments built a three-component t-SNARE on one vesicle population to interact with a unitary v-SNARE on another. It is known that the four-helix bundle can also be formed in solution from soluble cytoplasmic domains of SNARE proteins. However, there are topological constraints on SNARE interactions when confined to membranes, which are not imposed in solution. On varying the distribution of each of four cognate SNAREs between donor and acceptor vesicles, Parlati et al. found that the original combination of Bet1 (v-SNARE) liposomes with Sed5–Bos1–Sec22 (t-SNARE complex) is uniquely fusogenic. Thus, the distribution of cognate SNAREs between partner membranes determines fusion specificity. This is important because the cellular distribution of SNARE proteins is not static.

7.4
Regulation of SNARE Complex Assembly

What is the effect of including a fifth SNARE in the liposome fusion system? In most cases, this has no effect, but instances have been found in which the additional SNARE can compete with and substitute for a fusogenic subunit, thereby inhibiting fusion. Components of the cis-Golgi fusion machinery are inhibited by components of the trans-Golgi machinery and vice versa. This has led to the concept of the inhibitory SNARE (i-SNARE). If SNAREs can regulate fusion in both a positive and negative manner, then this will provide tighter control of specificity at biological membranes containing overlapping SNARE complements. The ratio of fusogenic SNAREs to i-SNARES will determine propensity for specific fusion.

The N-terminal domain of the syntaxin-like SNARE proteins, such as neuronal syntaxin1 and yeast Sso1p, fold into three-helix bundles and inhibit SNARE pairing when folded back against their SNARE domains. In this configuration, syntaxin can form a tight complex with the neuronal SM protein (Sec1/Munc18 homolog) Munc18-1, but it must change to the ''open'' conformation to engage in SNARE complex assembly. This interaction with Munc18-1 has thus been proposed to inhibit syntaxin SNARE function, but this remains controversial. The proteins Munc13 and RIM have been proposed to promote synaptic vesicle fusion through displacement of Munc18-1 from syntaxin. Likewise, some tethering factors such as EEA1, known to interact with syntaxin family members, may also act to displace SM proteins and promote an open syntaxin configuration.

8
Vesicle Trafficking and Disease

The origins of many human pathologies lie in defective vesicle trafficking. In many cases, this is due to a specific failure of cargo selection. For example, hypercholesterolemia leading to atherosclerosis can result from mutations in the cytoplasmic domain of the LDL receptor required for endocytosis or in the LDL receptor–specific adaptor protein, ARH. The hypertensive Liddle's syndrome is due to

failure to endocytose epithelial Na+ channels. It has also been argued that various proteins are oncogenic because of crucial roles that they may play in downregulating activated growth factor receptors through endocytic trafficking to lysosomal degradative compartments. For example, the oncogene c-Cbl is an E3-ubiquitin ligase, which mediates monoubiquitination of activated tyrosine kinase receptors, such as EGFR. Ubiquitinated receptors are specifically selected for downregulation by inclusion into lumenal vesicles of endosomal multivesicular bodies that routes them to lysosomes away from the recycling pathway. Failure to direct receptors along this route will lead to retention of activated receptors and increased mitogenic signaling.

One would expect defects in the core components of vesicle budding and fusion to be lethal, but there are examples where heterozygosity or point mutations lead to specific pathologies. Knockout mice heterozygous for syntaxin 4 develop muscle insulin resistance, consistent with a role for this SNARE molecule in GLUT4 (glucose transporter) exocytosis. A point mutation in α-SNAP leads to a developmental defect in mice, known as *hydrocephaly with hop gait*, which is characterized by a reduced size in the cerebral cortex, owing to premature production of cerebral cortical neurons and depletion of the progenitor pool. This is accompanied by abnormal localization of many apical proteins implicated in regulation of cell fate in neuroepithelial cells.

A number of bacterial pathogens subvert the cellular trafficking machinery to fashion intracellular compartments conducive to their requirements. For example, *Legionella pneumophila* is a bacterial pathogen that infects eukaryotic host cells and replicates inside a specialized organelle that is morphologically similar to the endoplasmic reticulum (ER). The Legionella-containing vacuole acquires rab1 and the v-SNARE protein Sec.22b, which facilitate fusion of the vacuole with ER derived COPII vesicles, allowing formation of a specialized compartment that can support bacterial replication. The clostridial neurotoxins, botulinum B and tetanus toxin are zinc endopetidases, which cause paralysis through specific cleavage of the neuronal v-SNARE, synaptobrevin.

9 Conclusions

The basic components of the intracellular budding and fusion machineries have been identified through a combination of biochemistry and yeast genetics. Current frontiers are concerned with understanding the regulation of these components. For example, what special mechanisms allow a synaptic vesicle to be released within milliseconds of an elevated Ca^{2+} concentration and what then limits the release of vesicles at the synapse? There is an increasing awareness of the role of membrane traffic in disease due to inherited or acquired mutations and due to utilization of established routes or subversion of trafficking machineries by various pathogens such as viruses and bacteria.

Keywords

Amphiphilic Molecule
A molecule with both polar and nonpolar elements.

Cell Membrane or Plasma Membraneff
The boundary layer of a cell, composed of a mosaic of proteins in phospholipid bilayers, which is supplemented with cholesterol in animal cells.

Hydrophilic Molecule or Atom
A highly water-soluble polar molecule or atom.

Hydrophobic Molecule or Atom
A nonpolar molecule or atom that is highly soluble in organic solvents.

Liposome
A body consisting of an artificial lipid bilayer (or bilayers) enclosing an aqueous compartment (or aqueous layers).

Membrane Protein
An integral membrane protein is inserted into a lipid bilayer, and is called a transmembrane protein if exposed on both membrane faces, whereas a peripheral membrane protein is bound to one of the membrane surfaces.

Permeability ($cm^3\ s^{-1}$) of a Membrane for a Solute
The ratio between the flow across the membrane (mol s^{-1}) and the concentration difference (mol cm^{-3}).

Phospholipid Bilayer
Thin lamellae composed of two layers of phospholipid molecules oriented to contain a hydrophobic, oil-like interior and expose hydrophilic structures toward the aqueous phases.

Phospholipid Molecule
An amphiphilic molecule with two hydrophobic chains and a polar headgroup containing a phosphate group and choline, ethanolamine, serine, inositol, or a similar moiety.

Proteoliposome
Liposome containing one or more membrane proteins inserted into the bilayers.

Small hydrophobic or amphiphilic solutes, such as oxygen or drugs, partition into the lipid bilayer of a cell membrane, diffuse within it, and partition out from it. More polar molecules, for example, glucose, require the help of a membrane protein to traverse the membrane. Porins contain pores of passage, whereas facilitative transporters change conformation to let the substrate through the membrane. Ion channels allow regulated passage of anions or cations. These modes of passive transport are thermally driven toward lower substrate concentration. Active transport proteins concentrate a solute by the use of adenosine triphosphate (ATP) hydrolysis or by means of an ion gradient whereby ions passing through the transporter drive the uphill transport of the substrate. Xenobiotics are expelled from cells by active transporters, for example, P-glycoprotein. Endo- or exocytosis transports compounds across the cell membrane in vesicles budding off from or fusing with the membranes, respectively. Partitioning and transport are analyzed with cells or cell models.

1
Cell Membranes

1.1
Structure

A membrane (schematically shown in Fig. 1) separates the cell from its surroundings, yet allows contact across the barrier, and membranes form organelles within cells. The thin, flexible membranes are composed of membrane proteins imbedded in lipid bilayers essentially impermeable to ions and large molecules. Protons, small molecules such as water (H_2O) and oxygen (O_2), and larger amphiphilic molecules, such as anesthetics and drugs can pass the bilayers slowly, whereas transmembrane proteins control the selective uptake of nutrients and the export of metabolic products, regulate the balance of ions and solutes between the exterior and interior of the cell or transmit signals. Certain membranes collect or transform energy.

Phosphatidylcholine, -ethanolamine, and -serine are major lipid components of mammalian cell membranes (Fig. 2A), and contain two fatty acyl chains of 12 to 24 carbons, one saturated and one unsaturated, esterified to carbons 1 and 2, respectively, of a glycerol backbone, whereas carbon 3 is connected to a phosphate group, which in turn carries an alcohol (X in Fig. 2A) to form a polar headgroup. Other lipid components are the phosphatidylcholine analogue sphingomyelin, which contains amide bonds instead of ester bonds, and cholesterol (Fig. 2B), with four fused sterol rings bearing a single hydroxyl group on ring A and a branched hydrophobic tail on ring D. The phospholipid/cholesterol bilayer of an animal cell membrane is approximately 4.5-nm thick and exposes the polar phospholipid headgroups on each face of the

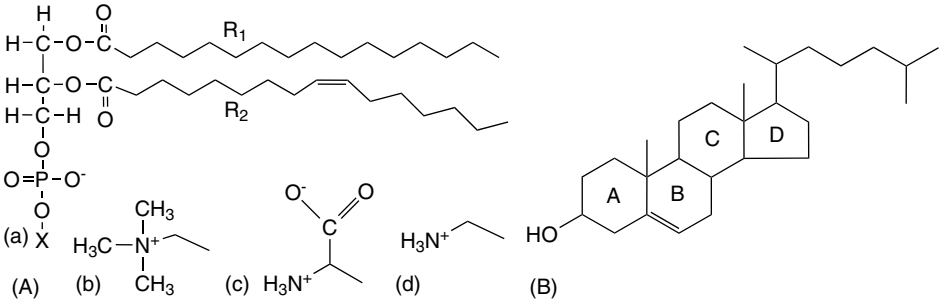

Fig. 2 (A) (a) Chemical structure of a glycerophospholipid with two 16-carbon chains where R_1 is saturated and R_2 is unsaturated with a double bond. X can be, for example, (b) choline, (c) serine, or (d) ethanolamine. (B) Cholesterol. The four fused rings are denoted A to D.

membrane. The overall structure of a lipid bilayer resembles the structure of a double layer of crystalline phospholipid, such as that determined by X-ray diffraction in Fig. 3, except that the lipids rotate, move their chains, and diffuse laterally in the liquid-crystalline phase, which solidifies to a gel-like consistence when the temperature is decreased below a transition temperature that depends mainly on the degree of unsaturation. Refinement of X-ray and neutron scattering data show the mobility of the various parts of the phospholipid molecules in the different regions of the membrane. They move in and out from their average position within certain limits. The fluidity of the membrane is modulated by cholesterol molecules, each one with its hydroxyl group in one of the two outer polar membrane regions and its rigid sterol skeleton in one half of the hydrophobic oil-like liquid in between the polar surfaces.

Integral or transmembrane proteins (which may be monomeric, dimeric, or oligomeric) are inserted into the phospholipid bilayer. Most mammalian integral membrane proteins are designed as a hydrophobic bunch of α-helices, each one containing about 20 amino acid residues and connected by hydrophilic loops. An individual three-dimensional structure allows a specific function for each protein, such as signal transduction, nutrient transport, or transport of xenobiotics across the membrane. Other membrane

proteins of entirely different structures (peripheral membrane proteins) are coupled to the membrane surfaces one by one or in chains forming cytoskeletal fibrous networks.

1.1.1 **Measurements Indicating the Membrane Structure**

The osmotic properties of plant cells were studied during the last half of the nineteenth century. Overton suggested (in 1899–1900) that the osmotic barrier of the cell consisted of a membrane "impregnated" with lipids of properties similar to cholesterol esters and phospholipids. The lipid–protein structure of cell membranes was debated during the first seven decades of the twentieth century. In 1925, Gorter and Grendel used a Langmuir trough to determine the surface area of a monolayer of the lipids extracted from one red blood cell. Calculations involving two errors that fortuitously cancelled each other indicated that the lipids formed a bilayer in the cell membrane. In 1972, Singer and Nicolson proposed, on the basis of thermodynamic considerations, that the hydrophilic and hydrophobic properties of membrane components and experimental data on cell membranes were consistent with a "fluid mosaic" membrane model with proteins inserted into and floating around in a phospholipid bilayer (Fig. 1). One of the observations supporting this model is the random spreading of the Rh_0(D) integral membrane protein molecules of the human red blood cell over the membrane as revealed by electron microscopy following ferritin staining of the Rh_0(D) proteins by using antibodies. This view has essentially persisted since then, although peripheral membrane proteins are associated with the membrane, some integral membrane proteins are coupled to cytoskeletal networks of proteins at the membrane surface or in the cytoplasm, and many integral membrane proteins are dimers or oligomers of one or more subunits. In 1975, Henderson and Unwin described the three-dimensional structure of the small light-driven proton pump, bacteriorhodopsin, according to electron diffraction data collected from crystalline patches, called purple membranes, of this transmembrane protein in

Halobacterium halobium. The first detailed X-ray crystallographic three-dimensional structure of a transmembrane protein, the big photosynthetic reaction center, which is involved in photosynthesis in *Rhodopseudomonas viridis*, was presented in 1985 by Deisenhofer, Huber, and Michel. The development of genetic techniques and the high stability and availability of bacterial membrane proteins has transferred the emphasis of the crystallographic membrane research to such proteins. These show close resemblance to human transmembrane proteins in the few cases that, so far, have been more closely studied. One example is the similarity between the *Escherichia coli* lactose permease, a membrane protein that mediates lactose transport across the inner bacterial membrane, and the human facilitated glucose transporter GLUT1.

2 Transport Across Cell Membranes

Solutes enter or leave a cell (Fig. 4) by partitioning into and diffusing across the bilayer, by protein-mediated transport or by endo- or exocytosis. Small amphiphilic molecules, for example, most orally administered drugs, may use the nonspecific partition-diffusion transport (Fig. 4a,b), which slows down with decreasing temperature but cannot be stopped. Small hydrophilic solutes diffuse through passages between the cells in cell layers; this is called the paracellular route (not illustrated). Ions and polar molecules partition only weakly into the hydrophobic region of the membrane and are helped by transmembrane proteins to pass the membranes at a high rate. Such transport proteins (Fig. 4c) either provide nonselective pores or offer specific binding, passage, and release of the substrate. Depending on the type of organism or organ, the transport is either passive, toward a lower solute concentration, or active, that is, concentrating the solute by use of an energy source, for example, adenosine triphosphate (ATP). Alternatively, a gradient of protons or other ions in one direction can be utilized to drive a cotransport of the solute toward higher concentration and the ion toward lower concentration.

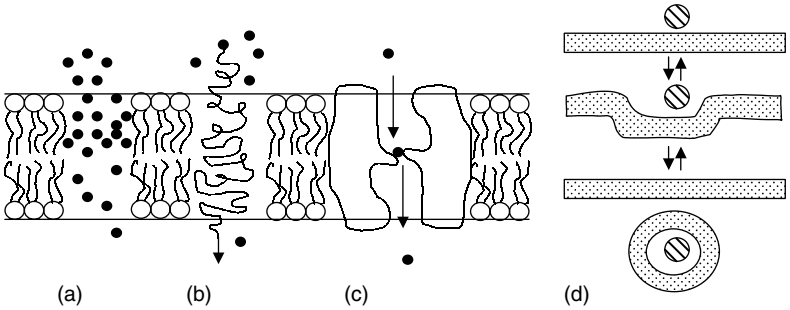

Fig. 4 Schematic illustrations of the permeation of a solute across a cell membrane by (a,b) partition–diffusion through the lipid bilayer (for clarity the lipid molecules are not drawn where the solute resides), where (a) exemplifies the concentration gradient formed, and (b) depicts the Brownian motion of a single solute molecule, (c) diffusion through a pore or channel of a membrane protein or facilitated diffusion mediated by a substrate-binding membrane protein, and (d) endo- or exocytosis.

Active multisubstrate transporters, such as the P-glycoprotein, expel xenobiotics from cells and cell organelles. Endo- and exocytosis are involved in the import and export, respectively, of certain molecules, for example, lipoproteins (Fig. 4d). The research on the many essential functions of membrane lipids and proteins has been hampered by methodological problems due to the insolubility of most membrane components in water.

2.1 Partition-diffusion

The molecules or atoms in gases or liquids move and collide randomly because of their thermal energy. Molecules that are nonrandomly distributed will move from a higher concentration toward a lower concentration because a collision is more probable where the molecules are closer to each other. This is diffusion, which also occurs in the semiliquid interior of a biological membrane. Solute diffusion in and across lipid bilayers is sometimes called simple diffusion, partition-diffusion, or nonfacilitated diffusion, to distinguish the process from facilitated diffusion; a thermally driven solute transport by a membrane protein toward a lower concentration.

2.1.1 Theory and Examples

The diffusional flux, J, (mol s^{-1}), of molecules from a region of high concentration toward regions of lower concentration can be expressed by Fick's first law of diffusion,

$$J = -D\frac{dc}{dx} \qquad (1)$$

with D, the diffusion coefficient (cm^2 s^{-1}); and dc/dx, the concentration gradient, that is, the derivative of the solute concentration with regard to the distance across the membrane. In the case of diffusion, across a membrane forming a hydrophobic barrier, Equation 1 can be written

$$J = \frac{A \times D_m \times \Delta C_m}{d} \qquad (2)$$

with A, the area (cm^2) of the membrane; d, the thickness (about 3×10^{-7} cm) of the hydrophobic region; D_m, the diffusion coefficient of the solute in the hydrophobic region; and ΔC_m, the concentration difference of the solute across the hydrophobic region.

A solute partitions between the hydrophobic region of a membrane and the water (Fig. 4a). At equilibrium, the solute concentrations within and outside the membrane balance the energy change as the solute crosses the boundary. The partition coefficient, K, is defined as the ratio between the solute concentrations in the nonpolar and aqueous phases. Therefore,

$$\Delta C_m = K \times \Delta C_{aq} \qquad (3)$$

with ΔC_{aq}, the concentration difference between the water on each side of the membrane.

The permeation of a small, hydrophilic molecule is slow because of weak partitioning into the membrane, creating a shallow concentration gradient within the membrane. More hydrophobic compounds partition more strongly into the membrane, but may suffer from a low aqueous solubility. Amphiphilic compounds thus require a certain balance between the amount and distribution of hydrophilic and hydrophobic structural features in order to permeate a membrane quickly.

A correlation between the partition and permeability coefficients for many solutes has been observed for a long time. In

the partition–diffusion model, K and D_m determine the rate of solute migration across a membrane. The permeability coefficient, P_s (cm s^{-1}), for the solute S is given by

$$P_s = \frac{D_m \times K}{d} \quad (4)$$

and the permeability, $P_s \times A$, equals the flux J (mol s^{-1}) of S divided by the concentration difference, ΔC_{aq} (mol cm^{-3}). For example, the permeability coefficient for glucose is 2×10^{-10} cm s^{-1} and that for O_2 is 2×10^{-3} cm s^{-1}. D_m is approximately 10^{-8} cm^2 s^{-1} for glucose and 0.5×10^{-5} cm^2 s^{-1} for O_2. Equation 4 thus requires that the membrane–water partition coefficient of oxygen is 10^4-fold that of glucose.

A solute that enters or leaves the membrane interacts with the electric charges and dipole moments of the polar headgroup region of the lipid bilayers, of oriented water molecules, of the carbonyl oxygens of the fatty acyl chains and of membrane proteins. Upon steady state transport, the solute concentration, therefore, varies nonlinearly across the membrane and also laterally, which complicates the situation described by Equations 2–4 and affects different transported compounds in different ways. Very small molecules may diffuse at an enhanced speed in the membrane by jumping through empty spaces between the lipid molecules.

The partition coefficient, K, can be expressed in the free energy change, $-\Delta G$:

$$K = e^{\frac{-\Delta G}{RT}} \quad (5)$$

with R, the general gas constant and T, the temperature. ΔG can be described by a hydrophobic-effect term and four electrostatic terms: the Born energy of transfer of an ion or dipole into a hydrophobic solvent; the image energy owing to the thinness of the membrane; the dipole-potential energy caused by the polar headgroup region; and the energy change upon the formation or breakage of hydrogen bonds and the binding or release of hydrating water. The partition–diffusion model works for hydrated ions, although cations may pass thin bilayers through transient pores and H^+ may be transferred along water strands in transient defects of the bilayer.

The equilibrium ratio between the concentrations of an ionic compound on each side of a membrane is directly affected by the transmembrane potential. A 10-fold concentration ratio of a univalent ion balances a 59-mV potential difference and a 100-fold ratio corresponds to twice that potential difference.

2.1.2 Measurements

The partitioning of solutes into lipid bilayers or cell membranes can be determined by chromatography on liposomes, proteoliposomes, membrane vesicles or cells adsorbed to or entrapped in gel beads packed into columns. This is called immobilized-liposome chromatography or immobilized-biomembrane chromatography (ILC, IBC). The chromatographic retardations of the solutes divided by the lipid amount in the column provide partition data, which correlate with octanol-water (P_{oct}) partition data, as do solute partition data obtained by pH titration of the solute in a liposome suspension, or by optical surface-plasmon resonance analysis of solute binding to liposomes coupled to a planar surface. These techniques reveal details of solute interactions with membranes. The partitioning of drugs into lipid bilayers decreases in the order neutral, positively charged, and negatively charged drugs compared to partitioning into octanol. Cholesterol in the bilayers

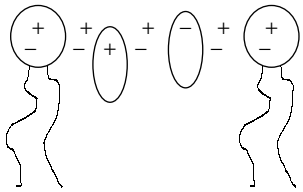

Fig. 5 Proposed distribution of positively and negatively charged amphiphilic solute molecules at the interface between the polar and nonpolar regions of the membrane. The lower half of the solute molecule is thought to be predominantly hydrophobic. Electrostatic effects cause different distributions of the two charged solutes, and thereby stronger or weaker hydrophobic effect.

decreases the partitioning in proportion to its amount. Membrane proteins enhance or decrease the partitioning by electrostatic interactions in combination with hydrophobic partitioning; and positively charged drugs partition relatively strongly into the hydrophobic region of the bilayer, whereas negatively charged drugs tend to dissociate more rapidly from liposome surfaces (Fig. 5). The simpler model of drug partitioning into a layer of $(oxyethylene)_{23}$ dodecyl ether molecules adsorbed to a stationary phase to mimic the membrane structure upon micellar liquid chromatography shows strikingly high correlations with ILC/IBC partitioning data obtained for a set of drugs on liposomes, red blood cell membrane vesicles, red blood cells, and ghosts.

A number of methods for permeability measurements are available. The permeabilities of cell membranes for solutes determined by observations of osmotic swelling or shrinking of cells by microscopy or weighing correlate rectilinearly with the oil–water partitioning or with P_{oct} of the osmotically active solutes. The permeability of liposomes for protons has been determined by measuring the pH-dependent fluorescence of pyranine, a cation-sensitive electrode has been used for potassium ions, and light-scattering analysis of osmotic swelling by use of a stop-flow apparatus has been used for water, glycerol, and urea. The liposomal and proteoliposomal permeabilities for radioactively labeled glucose, tyrosine, and tryptophan have been estimated by incubation followed by size-exclusion chromatographic separation monitored by flow-scintillation detection. The permeability coefficients for α-substituted *p*-toluic acids and glucose have been determined by incorporation into liposomes, removal of the free compound by size-exclusion chromatography, collection of the compound released during incubation by ultrafiltration and determination of the amount of the transported compound by high performance liquid chromatography (HPLC).

In the pharmaceutical industry, the use of sealed monolayers of cultured epithelial tumor cells, for example, Caco-2 cells, has achieved a widespread practical application in the determination of permeabilities. The drawbacks are inconsistency among permeability values determined in different laboratories and the time-consuming culturing of the cell layers.

2.2 Diffusion through Porins

Pore-forming proteins, called porins, provide openings that allow diffusional passage of polar molecules of moderate size. There are 10 families of aquaporins that let water pass rapidly through membranes. Such a protein, in red blood cells is

a tetramer of M_r 28 000-subunits, each containing six transmembrane α-helices forming a barrel that leads to a water-selective pore, which does not allow ion passage. The pore contains a hydrophobic section with three widely separated hydrophilic sites. Aquaporins in kidney cell membranes are involved in the reabsorption of 150 l of water per day.

In the outer membrane of gram-negative bacteria, for example, *E. coli*, porins provide openings that allow diffusional passage of polar molecules of M_r up to about 600. These porins are trimers of hollow cylinders, β-barrels, with a hydrophobic belt on the outside in contact with the fatty acyl chains of the surrounding phospholipids. The pores are hydrophilic and water-filled with protruding amino acid side chains that limit the size of the solutes that can pass by diffusion toward lower concentration. Similar size-selective porins are also found in the outer membrane of mitochondria.

The efflux of a variety of antibacterial components, including protein toxins, from *E. coli* and other gram-negative bacteria takes place by interaction between inner-membrane proteins and an outer-membrane TolC protein that spans both the membrane and the periplasmic space with a 14-nm tunnel, offering a transport mechanism similar to that of the porins, which span the outer membrane only. However, the tunnel can be sealed and unsealed to regulate the transport.

2.3 Diffusion through Ion Channels

2.3.1 Chloride Channels

Chloride channels allow the passage of different anions, of which chloride is physiologically the most common. The channels are divided into three classes, the dimeric chloride channels (ClC), the cystic fibrosis transmembrane conductance regulator (CFTR) and the ligand-gated GABA and glycine receptors.

The chloride/hydrogen carbonate (anion) exchange protein of human red cells has been studied for decades and the sequence was deduced in 1985. A bacterial ClC has been crystallized and shows a complex pattern of 18 tilted α-helices. The ClC in the electric fish *Torpedo* contains two gated barrels that open and close independently to give three conductance levels, zero (both closed), medium (one open), and high (both open). The same behavior is shared by the muscle chloride channel expressed in oocytes from the African tree frog, *Xenopus laevis*.

The special CFTR type of chloride channel that regulates salt and water transport across epithelial tissue is an ATP binding cassette (ABC) transport protein activated by phosphorylation of a cytoplasmic domain by protein kinase A. Cystic fibrosis is caused by decreased CFTR activity in the lung and secretory diarrhea is caused by increased CFTR activity in the gut.

2.3.2 Na^+, Ca^{2+}, and K^+ Channels

Voltage-dependent channel proteins that allow passage of Na^+, Ca^{2+}, or K^+ are tetramers of identical or similar subunits. The three-dimensional structures of potassium channel domains have recently been solved by X-ray crystallography and NMR spectroscopy. In the known K^+ channels, the "pore-forming region" of each subunit joins with its neighbors in the tetramer to constitute a channel. In *Streptomyces lividans*, the short K^+-ion selective part of the channel is lined with carbonyl oxygen atoms and accommodates two non-hydrated K^+ ions at a time, whereas Na^+ ions are too small to fit. A wider cavity of

the K^+ pathway is surrounded by helix-end dipoles.

2.4 Facilitated Diffusion

Many solutes are transported passively and selectively by so-called facilitated transporters. Such transmembrane proteins seem to consist of multi-α-helical hydrophobic regions with connecting hydrophilic loops, and the various transporters form large families of related membrane proteins from different organisms and organs with various substrate specificities. As for passage through porins and ion channels, the driving process is thermal diffusion toward lower concentration. However, the facilitated transport involves recognition and binding of the substrate, with a strictly limited range of allowed substrates for each protein. Facilitated diffusion reaches a saturation rate at high substrate concentration and can be competitively inhibited. The basic kinetic equation resembles the Michaelis–Menten equation for the rate of enzymatic reactions. The flux, J, depends hyperbolically on the substrate concentration, C:

$$J = \frac{J_{\max} \times C}{K_m + C} \qquad (6)$$

with $J_{\max}$, the maximal flux and K_m, the substrate concentration at half the maximal flux, equivalent to the Michaelis–Menten constant.

2.4.1 Examples

Detailed studies of the kinetics of transport of certain solutes have been carried through in red blood cells and model systems, for example, with GLUT1, which transports D-glucose and other monohexoses, particularly in red blood cells, epithelial cells, and the blood-brain barrier. Low expression of GLUT1 or truncation of the protein, in two infants, has been shown to lead to a low glucose concentration in the cerebrospinal fluid and delayed development and seizures; owing to insufficient transport of glucose across the blood-brain barrier. The single subunit of this oligomeric protein probably contains 12 transmembrane α-helices. GLUT1's basic functional unit is the dimer, in which both the subunits switch 100 to 1000 times per second between two alternative conformations in a synchronized way, such that one subunit can bind a substrate molecule while the other can release another substrate molecule (Fig. 6). The thermal energy seems to be too low to drive the oscillations between the two states in a single, separate monomer, but the coupled mechanism of the conformational switches in the dimer may provide a much lower activation energy. Another mechanism involving evaporation and condensation of water in the glucose-binding spaces has been proposed. The three-dimensional structure of the protein is unknown, but a model structure has been designed by combining biochemical and mutagenesis data for GLUT1 with established similar data for a related active transporter, the lactose permease from *E. coli*. The packing of the 12 helices was deduced mainly from site-specific mutagenesis experiments. The GLUT1 model indicated the existence of a hydrophilic pore with two deeply embedded glucose-binding sites.

The blood glucose level is partly regulated by insulin. In muscle and fat cells, the GLUT4 glucose transporter, which is closely related to GLUT1, can be recruited from internal membrane systems to the cell membrane to enhance the rate of glucose transport. Insulin binds to a receptor in the cell membrane and

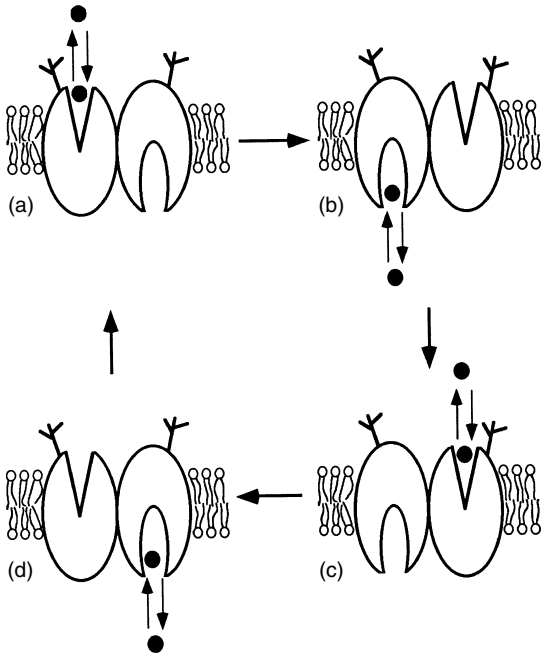

Fig. 6 The dimeric alternating-conformation model of facilitated glucose transport by GLUT1. Each subunit is shown with its oligosaccharide and, in each moment, a single substrate-binding site. The subunits are coupled to each other in the way that the change from outward- to inward-facing binding site of one subunit occurs together with a change in the opposite direction for the other subunit. (a) Glucose binds to the outward-facing site of one subunit (left), the conformation switches, and (b) the glucose molecule is released. (c) Glucose binds to the other subunit (right), the conformation switches, and (d) the glucose molecule is released. Next, the binding in (a) is repeated, and so on. Also, in the absence of glucose, the conformation alternates between the two conformations. The competitive inhibitor cytochalasin B binds only to the inward-facing opening and the number of cytochalasin B-binding sites is one per dimer in the native protein.

triggers the migration of vesicular internal membranes containing GLUT4 to the cell membrane, with which the vesicles then fuse. Too low insulin concentrations, or failure of the insulin receptor to convey the insulin signal to the vesicle migration system may cause diabetes of type 1 in children, or type 2 in adults or elderly persons, respectively. The response to insulin is also modulated in other ways, for example, by the lack of a membrane protein called FAT/CD36, whereby fatty acid uptake in various tissues decreases strongly.

The transport of cholesterol and phospholipids from the high-density lipoprotein (HDL) into the brush border membranes of the small intestine is mediated by receptor proteins. HDL binds to proteins in the membranes for the transfer of the lipids. HDL also absorbs cholesterol diffusing from cell membranes or transported out of the cell by facilitated diffusion, thereby protecting against cardiovascular diseases. Low-density lipoprotein (LDL) transfers cholesterol into cells by receptor-mediated endocytosis (Sect. 2.6).

Certain "equilibrative" nucleoside transporters are very similar to the GLUTs. Two cDNAs from placenta encoding two such transporters have been expressed. These proteins are predicted to contain 11 hydrophobic transmembrane α-helices. One of the transporters was inhibited by nitrobenzylthioinosine and facilitated the transport of adenosine and chemotherapeutic nucleosides.

Nucleotide sugars are transported across the membranes of the endoplasmic reticulum and the Golgi compartments in eukaryotic cells in exchange for nucleoside monophosphates to serve in the glycosylation of proteins and lipids.

Among amino acid transporters, the system L for large, neutral amino acids

is an unusual, facilitated system, which appears as a heterodimer containing a cell-surface glycoprotein. Transport of the essential amino acid tryptophan and of tyrosine, both of which are precursors of signal substances in the brain, is mediated by the recently discovered TAT protein.

2.4.2 Measurements

Facilitated diffusion can be analyzed by the use of cells, cell membrane vesicles, or proteoliposomes, which are incubated with radioactively labeled substrates in most types of analyses. This closely resembles permeability measurements discussed briefly in Sect. 2.1.2, although the facilitated diffusion usually is much more rapid and allows the use of inhibitors. Both these circumstances make the determinations relatively easy. Human red blood cells or *X. laevis* oocytes have often been used. The oocytes allow expression of membrane proteins that they normally do not contain. The transport is stopped by the use of an inhibitor, if available, and the cells and so on that contain the transported substrate are separated from free substrate by centrifugation, filtration, or size-exclusion chromatography. The radioactive substrate may be added outside the cells and so on, for determination of inward transport, or loaded inside before washing to determine outward transport. For equilibrium exchange measurements, the substrate is present on both sides of the membrane at the same concentration, whereas the radioactive tracer is added to one side only.

2.5 Active Transport

In contrast to the passive facilitated diffusion, which uses thermal energy only, active transport of certain substances, for example, sodium and calcium ions, amino acids, and sugars, against their concentration gradients requires chemical energy provided by hydrolysis of ATP; light energy, as in the purple membrane (primary active transport), or energy supplied indirectly by the electromotive force of an ion gradient (secondary active transport). In the latter case, the concentrated substrate is cotransported with an ion. The two transported entities can either migrate in the same direction through a transporter called symport, or in opposite directions through an antiport.

2.5.1 Examples

A primary active transporter is the P-type (Na^+, K^+)-ATPase, which transports sodium ions in one direction, out from the cell, and potassium ions in the opposite direction, both against the concentration differences, by use of energy obtained by hydrolysis of ATP. Similarly, as for facilitated diffusion, a Michaelis–Menten constant, K_m, can be assigned to each of the ions and to each of the components, ATP, adenosine diphosphate (ADP), and phosphate ions. The protein is composed of α/β-heterodimers of an α-subunit containing 10 transmembrane α-helices with the longest connecting loop between helices 4 and 5, and a β-subunit with a single transmembrane helix and a relatively long periplasmic polypeptide chain with three Cys–Cys cross-links. The α-subunit seems to alternate between two distinctly different conformations.

The (Na^+, K^+)-ATPases form one group of cation transporters together with the closely related Ca^{2+}-ATPases (Fig. 7). One of these autophosphorylated, P-type, ATPases of M_r 110 000 pumps Ca^{2+} released in skeletal muscles back into the sarcoplasmic reticulum. This protein has

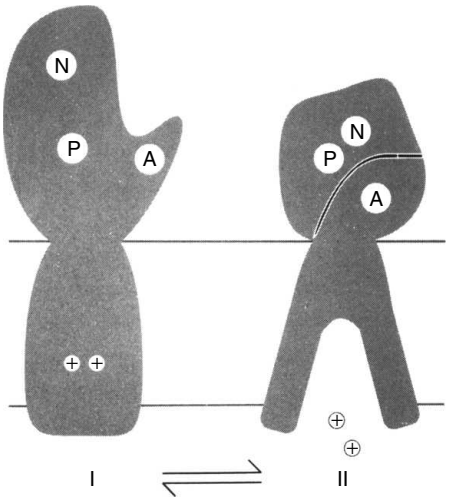

Fig. 7 Mechanism of a P-type ATPase. A schematic drawing of the conformational changes in the α-subunit of the sarcoplasmic reticulum Ca^{2+}-ATPase upon ion transport. This transporter has been crystallized and the structure was solved. It is thought to be closely similar to Na^+, K^+-ATPases. P, phosphorylation domain, A, actuator domain, and N, nucleotide binding domain. To the left (I) the protein is open to the cytoplasm but closed to the A domain. In (II), the protein is open to the membrane but closed to the cytoplasm. The change from I to II involves motion of the N and P domains toward each other and a rotation of the A domain. Reprinted with permission from J.H. Kaplan and the copyright owner. From Kaplan, J.H. (2002) Biochemistry of Na,K-ATPase, *Annual Reviews of Biochemistry*. **71**, 511–535. Copyright 2002 by Annual Reviews, www.annualreviews.org.

been determined by X-ray diffraction analysis of protein crystals to consist of a single subunit with 10 transmembrane α-helices. The phosphorylation and adenosine-binding sites reside on separate cytoplasmic domains.

Another type of primary active transporters, the ABC transporters, belong to a family of proteins that translocate various substrates across cell membranes. They contain two transmembrane domains forming a pathway for the substrate and two ABCs, which cause a conformational change of the pathway, effecting translocation of the substrate, by use of the energy dissipated upon hydrolysis of ATP to form ADP.

There are several ABC multidrug-resistance proteins, for example, the P-glycoprotein and MRP1 (multidrug resistance protein 1). The P-glycoprotein, a membrane protein with M_r of about 170 000, works as a dimer of two homologous subunits with six transmembrane helices and one ATP binding domain per subunit. The protein transports many substances, such as xenobiotics, which have in common that they are quite hydrophobic and, therefore, accumulate in the membrane, have an M_r of 300 to 2000, and are neutral or positively charged at pH 7. At least four transport and regulatory binding sites exist, which are able to switch between high and low affinities. Only one of the ABCs hydrolyzes ATP at a time and ADP release may be rate limiting. These transporters cause problems in cancer therapy. The cancer cells become resistant to certain drugs upon overexpression of the P-glycoprotein, or other such transporters, which extrude the drugs from the cells. These proteins are also widely distributed in normal tissues, for example, in liver, intestine, and kidney.

The crystal structure has been determined for another ABC transporter, the BtuCD protein in *E. coli*, which mediates vitamin B_{12} uptake through a

transmembrane dimer containing, in all, 20 helices. ATP binding to each of the cassettes and ATP hydrolysis cause an opening of the vitamin B_{12} pathway toward the cytoplasm.

The lactose permease from *E. coli* belongs to the secondary active transporters and is a functionally monomeric H^+/lactose symport. One neutral and five charged amino acid side chains in transmembrane helices cannot be replaced in order to preserve the transport as was shown by genetic-engineering replacement of all amino acid residues, one by one, by a cysteine residue. The expression of the protein is regulated by the presence of glucose and other sugars via a mechanism involving cyclic adenosine monophosphate (cAMP). Two-dimensional crystals have been formed of both lactose permease with cytochrome b_{562} introduced in a cytoplasmic loop and of a transmembrane subunit of the *E. coli* glucose transporter. Trimers and dimers, respectively, were observed by electron microscopy techniques.

Two-dimensional subunit crystals have also been prepared of another type of sugar transporter, the phosphoenolpyruvate:carbohydrate phosphotransferase system (PTS), which transports hexoses and releases them as phosphorylated sugars that cannot leave the cell. The PTS transporter is preferentially used for sugar transport into the cell, and the amount of other sugar transporters is regulated accordingly.

Glucose can be actively taken up in the small intestine by a secondary Na^+/glucose symport. A Na^+ gradient created by a Na^+, K^+-ATPase drives the accumulation of glucose by the Na^+/glucose transporter. Another member of this Na^+/solute symport family is the high affinity choline transporter, which pumps choline into the presynaptic terminals of cholinergic neurons and thereby regulates the rate of acetylcholine synthesis. Changes in the function of cholinergic neurons are thought to be involved in Alzheimer's disease, Down's syndrome, Parkinson's disease, and schizophrenia.

2.5.2 Measurements

The primary active transport of nutrients and metabolites is determined similarly as passive transport, commonly by use of radioactive tracers. The ATP hydrolysis can be monitored by use of coupled reactions, for example, with pyruvate kinase and lactate dehydrogenase, or by use of separation followed by phosphorus analysis. Ion transport may be determined by the use of an ion-sensitive electrode, and the transmembrane potential and current can be monitored in the case of large cells or planar membranes. Fluorescent and light-absorbing probes sensitive to various parameters, such as pH, are useful tools.

2.6 Endo-, Exo-, and Transcytosis

Endocytosis imports molecules into the cell from the surrounding medium and exocytosis exports molecules from the cytoplasm out to the surroundings by budding off vesicles containing the molecules from the cell membrane or fusing such vesicles with the membrane (Fig. 4d). Receptor-mediated endocytosis is encountered in many cases, for example, upon internalization of LDL lipoproteins bound to LDL receptors in pits coated with the protein clathrin. The binding is followed

by an invagination of the cell membrane followed by the budding off of a membrane vesicle within the cell. In another example, receptors activated by the epidermal growth factor are internalized through clathrin-coated pits. Endothelial cells allow transcytosis of proteins by so-called cargo-vesicles and in transendothelial channels formed by such vesicles. These processes are mediated by protein machines. Exocytosis in eukaryotic cells involves an ''exocyst,'' a complex of eight proteins that enables the secretory vesicle to dock on and fuse with the cell membrane.

3
Transport Across Epithelia

3.1
Intestinal Epithelia

The gut absorbs water, nutrients, and certain ions while excluding bacteria and unwanted molecules. Active and passive transporters allow the uptake of sugars, amino acids, nucleosides, and small peptides. For example, glucose is actively absorbed into the epithelial cell by the Na^+/glucose symport and passes on into the blood by facilitated diffusion mediated by GLUT5. The gaps between the apical parts of the epithelial enterocytes are sealed by tight junctions, allowing the passage of small molecules only. The elimination of xenobiotics, such as drugs, is handled by P-glycoproteins that use ATP to drive expulsion of the foreign compounds that have generally entered the cells by partition–diffusion. Drugs are also metabolized by enzymes, for example, cytochrome P450 proteins. Cell lines, such as Caco-2, are cultured to form monolayers that resemble the intestinal epithelia, and P-glycoprotein expulsion of drugs can be observed as a lower permeation from the apical to the basolateral side (corresponding to transport from the gut to the blood), than in the opposite direction.

3.2
The Blood-brain Barrier

The blood-brain barrier (BBB) consists of the endothelial cells lining the capillary blood vessels in the brain and separates the blood from the extracellular matrix around the astrocytes. Tight junctions of high electrical resistance between the cells limit the paracellular flow, and the amount of endocytotic vesicles is low in the cells, which restricts the transcellular flow. Certain molecules are allowed into the brain by facilitated diffusion via membrane proteins, notably the brain fuel D-glucose, which enters through GLUT1, L-ascorbic acid (vitamin C), and certain amino acids and similar molecules (L-3,4-dihydroxyphenylalanine, L-DOPA). Vitamin C is transported into the brain in the choroid plexus by Na^+-dependent active transporters. Dehydroascorbic acid can be transported by GLUT1 to be reduced in the brain, but this pathway is physiologically unimportant. Even certain macromolecules are believed to enter the brain via a receptor-mediated mechanism, and *Streptococcus pneumoniae* and six more bacterial pathogens can interact with the endothelial cells in an unknown way that allows the bacteria to cross the barrier. The P-glycoprotein is present in substantial amounts in the endothelial cells and tries to eject back into the blood unwanted lipophilic molecules that have diffused into the brain or just into endothelial cells. The embryonic and postnatal development of the BBB is

still unclear, and the use of cultured endothelial cells to mimic the physiological properties of the BBB is haunted by difficulties.

4 Solute Affinities for Membrane Proteins

Biospecific interaction between a solute, for example, an inhibitor, and a membrane protein in cells, membrane vesicles, proteoliposomes or other lipid environments can be quantified by immobilized-biomembrane affinity chromatography. Entrapment in gel bead cavities and covalent binding of phospholipid analogues are examples of the immobilization methods used. The retardation of the front of an eluting large-volume sample of the solute reflects the solute affinity for the protein and the solute concentration. In simple cases, a series of runs at different solute concentrations allow calculation of the equilibrium constant and the number of binding sites, provided that the number of binding sites matches the affinity. The glucose transporter from human red blood cells and a recombinant P-glycoprotein showed constant interactant affinities for months in the columns. The solute retardation is caused both by partitioning into the membrane and by binding to active sites of the membrane proteins. Both effects can be measured. A competitor for the solute–protein interaction in the system will decrease the retention volume of the solute to a degree determined by its affinity for the protein. Ligand binding to membrane proteins can also be analyzed by surface-plasmon resonance, and, in some cases, by analysis of changes in the intrinsic fluorescence of tryptophan side chains or other spectral properties upon ligand binding to the protein. A number of related techniques exist, but the fact that most membrane proteins require a lipid environment for activity limits the choice.

5 Prediction and Modeling of Drug Absorption Across Membranes

Some basic requirements for oral administration of new drug candidates are sufficient solubility in water, reasonable partitioning into membranes, and a fair diffusion coefficient. The partitioning is commonly modeled in the pharmaceutical industry by octanol/water partitioning, expressed as the logarithm of the partition coefficient, log P_{oct}. The advantages of log P_{oct} are the vast amount of available data and the extensive experience of the applicability of these data. Lipinski introduced the ''rule of five,'' which can be used as a filter in early drug development. This rule predicts that poor absorption or permeability properties become likely when the drug molecule has more than five H-bond donors, more than 10 H-bond acceptors, when the M_r exceeds 500 and when the log P_{oct} is larger than 5.

Methods for experimental assessment of partitioning into membranes and permeability across membranes are required, although computer calculations are becoming increasingly popular for theoretical analysis. Computational methods for determination of absorption or permeability properties by statistical analysis often use molecular descriptors, such as the polar surface area of the drug and the number of H-bond donors/acceptors.

Molecular dynamics simulations are still at a primitive stage. For example,

computer modeling indicates that the diffusion coefficients of O_2 and H_2O are highest in the center of the membrane, 0.9×10^{-5} and 1.4×10^{-5} cm^2 s^{-1}, respectively. An analog (M_r 315) of the drug nifedipine, obtained by replacing NO_2 by CH_3, had a diffusion coefficient of 1.3×10^{-6} cm^2 s^{-1} all across the hydrophobic region of the membrane. Furthermore, pharmacokinetic problems tend to override the shortcomings of the computer predictions of drug absorption. Absorption is a complex process dependent on factors such as the permeability and solubility of the drug, and physiological factors such as pH, intestinal enzymology and motility, so the absorption is therefore not so easily predicted from the structure alone or from computer simulations of drug-membrane interaction.

6 Conclusions and Visions

The permeability of lipid bilayers or biological membranes for a given solute is generally difficult to determine experimentally and can only be estimated approximately from the chemical structure of the solute or by the use of partition data with either octanol–water or membrane–water. These approaches do not truly mimic the interactions between solutes and membranes. Partition analyses with water–membrane systems do not reveal the detailed solute distribution within the membrane that determines the gradient in solute concentration and thereby the solute flux across the membrane. The solute permeability of membranes may, in the future, be determined by use of sensitive detection in miniaturized devices. Calculations by use of the detailed structures of the solute and the membrane may become more accurate after advances in quantum chemical or physical–chemical methods. In the future, the transport kinetics and transport mechanisms of transmembrane proteins may be evaluated by small-scale permeability assays and advances in crystallization technology, or single-protein molecule diffraction analyses may allow determination of the three-dimensional structures of membrane proteins.

Keywords

Adenosine Triphosphate (ATP)
The "energy currency" of the cell. The energy derived from metabolism can be stored by synthesizing ATP from ADP and P_i, displacing the ATP hydrolysis reaction from equilibrium by many orders of magnitude. The energy stored in this displacement from equilibrium can then be used to do work as ATP is hydrolyzed back to ADP and P_i. Thus, the synthesis and hydrolysis of ATP link catabolic reactions with anabolic and work reactions in metabolism, and ATP acts as a short-term energy store.

ATP Synthase
The enzyme complex that catalyzes the synthesis of ATP from ADP and P_i. The ATP synthase makes use of the energy stored in the protonmotive force across the mitochondrial inner membrane. Protons move through the complex from the intermembrane space back into the matrix, catalyzing rotation of the central stalk (γ subunit) with respect to the catalytic α and β subunits, which synthesize ATP from ADP and P_i.

Glycolysis
The sequence of enzyme-catalyzed reactions in the cytosol that is the first stage in breaking down glucose to release its energy. The end product of glycolysis is two molecules of pyruvate per glucose, along with a small amount of ATP and reduced nicotinamide adenine dinucleotide (NADH). Pyruvate and electrons from NADH may be transported into mitochondria to be used as substrates for the TCA cycle and the respiratory chain, respectively.

Mitochondria
The central organelles of energy metabolism. Mitochondria are responsible for producing most of the cell's adenosine triphosphate (ATP). The tricarboxylic acid (TCA) cycle and β oxidation of fatty acids take place in mitochondria, as does electron transport by the respiratory chain, the process that drives ATP synthesis by the establishment of a protonmotive force across the mitochondrial inner membrane.

β Oxidation
The process by which fatty acids are broken down in mitochondria. Fatty acids are converted to fatty acyl CoA before entering the β oxidation cycle, which involves the sequential shortening of the fatty acyl chain by two carbons at a time, with the release of acetyl CoA and the concomitant reduction of the electron carriers NAD^+ and FAD to NADH and $FADH_2$, respectively. The acetyl CoA molecules enter the TCA cycle, while the NADH and $FADH_2$ are oxidized by the respiratory chain.

Oxidative Phosphorylation
The process by which the oxidation of carbohydrates and fatty acids by oxygen is coupled to the phosphorylation of adenosine diphosphate (ADP) to ATP. Oxidative phosphorylation occurs in mitochondria when the NADH and $FADH_2$ produced by the

TCA cycle and β oxidation are oxidized by the respiratory chain. The redox energy is conserved as a protonmotive force across the mitochondrial inner membrane, which is used to drive ATP synthesis by the ATP synthase in the mitochondrial inner membrane.

Protonmotive Force
A measure (in mV) of the proton electrochemical potential gradient across the mitochondrial inner membrane. The protonmotive force is generated by the pumping of protons by the mitochondrial respiratory chain, which in turn is driven by the release of redox energy from electrons as they pass through the chain. The protonmotive force is composed of a membrane potential ($\Delta\psi$) and a pH gradient (ΔpH) component. It is used by the ATP synthase to synthesize ATP and by the adenine nucleotide transporter (ANT) and phosphate (P_i) carrier to transport ATP, ADP, and P_i across the mitochondrial inner membrane.

Respiratory Chain
A series of protein complexes and mobile electron carriers in the mitochondrial inner membrane that translocates electrons down a gradient of increasing redox potential. The respiratory chain oxidizes the carriers NADH and $FADH_2$ and passes the electrons down the chain toward oxygen, using the redox energy differences to pump protons across the mitochondrial inner membrane. This enables the redox energy to be stored as a protonmotive force, which is then used to synthesize ATP from ADP and P_i.

Tricarboxylic Acid (TCA) Cycle
Also known as the *Krebs cycle* or the *citric acid cycle*. The TCA cycle is a sequence of enzyme-catalyzed reactions that occur in the mitochondrial matrix. Acetyl CoA (produced by the oxidative decarboxylation of pyruvate) acts as the entry point for the TCA cycle by fusing its two-carbon acetyl group with the four-carbon oxaloacetate to form the six-carbon citrate. Citrate is then sequentially oxidized by the various enzymes of the TCA cycle, losing two carbons as CO_2 to regenerate oxaloacetate while producing NADH and reduced flavin adenine dinucleotide ($FADH_2$), and also generating GTP by substrate level phosphorylation. Many other small molecules connect with the TCA cycle at various points, making the TCA cycle central for most of metabolism. The NADH and $FADH_2$ produced are oxidized by the respiratory chain to generate ATP by oxidative phosphorylation.

All cell processes require energy to carry out work, whether it be synthesis, replication, secretion, movement, or signaling. Consequently, a continuous supply of energy to the cell is essential for life. Ultimately, the energy for mammalian cells is provided by the breakdown of food. In order to make this chemical energy available to the cell in a form that can do many different kinds of work, a common intermediate is required. This energy intermediate is the displacement from equilibrium of the

ATP $\rightleftharpoons$ ADP + P_i reaction. Within our cells, this reaction is displaced from equilibrium by increasing the ATP concentration relative to that of ADP by several orders of magnitude, making approximately 50 $kJ.mol^{-1}$ of energy available from the hydrolysis of ATP to do work. Maintenance of this displacement from equilibrium requires the continued expenditure of energy supplied by food. Carbohydrate derivatives and fatty acids are broken down and oxidized by a series of reactions within mitochondria. Released electrons are transferred to NAD^+ and FAD, reducing them to NADH and $FADH_2$. In turn, these electron carriers are oxidized by the respiratory chain in the mitochondrial inner membrane, using the oxygen we breathe as the final electron acceptor. The action of the respiratory chain pumps protons across the mitochondrial inner membrane so that the redox potential energy is stored as an electrochemical potential gradient, or protonmotive force, across the mitochondrial inner membrane. The protonmotive force is then used to drive the synthesis of ATP from ADP and P_i and to export the ATP from the mitochondria into the cytoplasm. This process, called *oxidative phosphorylation*, maintains the displacement from equilibrium of the ATP $\rightleftharpoons$ ADP + P_i reaction and is central to cellular energetics.

1
Cellular Energetics: Displacement from Equilibrium, Coupling, and the Role of ATP

Living things are distinguished by the displacement from equilibrium of a myriad biochemical reactions. Indeed, one way of describing death is as a return to equilibrium. Why is displacement from equilibrium a necessity for life? Consider how potential energy is stored in a hydroelectric dam or in a tightly coiled spring. In a similar way, displacement from equilibrium provides a means of energy storage within the cell; indeed, it is only by being displaced from equilibrium that biochemical reactions can store energy that can be used to carry out cellular work such as movement, replication, growth, and repair.

Living things require large amounts of energy to maintain the displacement from equilibrium of chemical reactions within the cell. In mammals, the energy source is food, and the chemical energy stored in food is released through the reactions of metabolism. Metabolism comprises a series of catabolic reactions that break down food, releasing precursor molecules and energy for maintaining the displacement from equilibrium that drives anabolic reactions and work. The energy released by the catabolic reactions of metabolism must be available in a form that can do the work of the cell. A central concept underlying this process, and all of energy metabolism, is "coupling," by which the energy released from food drives otherwise unfavorable reactions. How this energy coupling occurs is the focus of this chapter.

1.1
Coupling Drives Energetically Unfavorable Reactions

By coupling together favorable and unfavorable chemical reactions, it is possible to use the energy stored in food to drive

the cellular processes that comprise life. Thermodynamics indicates whether or not a reaction will occur spontaneously and gives the energy change associated with the reaction. In biology, the Gibbs free energy change (ΔG; $kJ.mol^{-1}$) is used. For spontaneous reactions, there is a release of free energy, so $\Delta G < 0$. In contrast, reactions that do not occur spontaneously have a ΔG greater than zero and require energy input to take place. In biological systems, there are many such processes, including synthesis, movement, replication, or signaling, that are thermodynamically unfavorable and cannot occur without an energy input. Fortunately, such unfavorable reactions can be driven by coupling them to a reaction with a favorable (negative) ΔG. This is illustrated below where the unfavorable reaction 1 is driven by reaction 2.

Reaction 1	$A \rightarrow B$	$\Delta G_1 > 0$
Reaction 2	$C \rightarrow D$	$\Delta G_2 < 0$
Overall	$A + C \rightarrow B + D$	$\Delta G_1 + \Delta G_2 < 0$

This process, by which an unfavorable reaction is made possible by coupling it to a favorable reaction, is central to the bioenergetics of living organisms. The energy flowing through our cells and bodies (derived from favorable catabolic reactions) is coupled to drive unfavorable

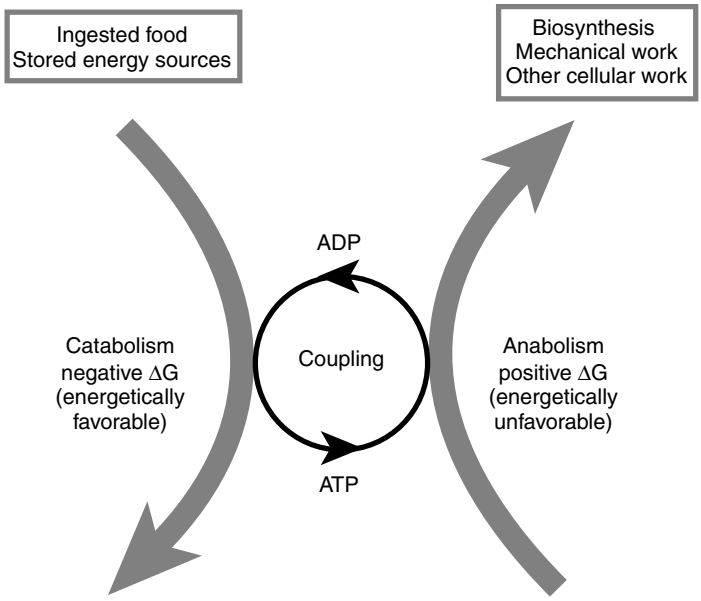

Fig. 1 The concept of coupling in mammalian energy metabolism. Energy is released by the breakdown of carbohydrate, fat, and protein, either from ingested food or from stored energy sources. Released energy is ''coupled'' to the otherwise unfavorable formation of adenosine triphosphate (ATP) by the addition of inorganic phosphate (P_i) to adenosine diphosphate (ADP). In turn, ATP hydrolysis to ADP and P_i (a highly favorable reaction) is coupled to unfavorable anabolic reactions, enabling them to take place. The Gibbs free energy change (ΔG) is used here to indicate whether a reaction is favorable (spontaneous) or unfavorable (requiring energy input through coupling).

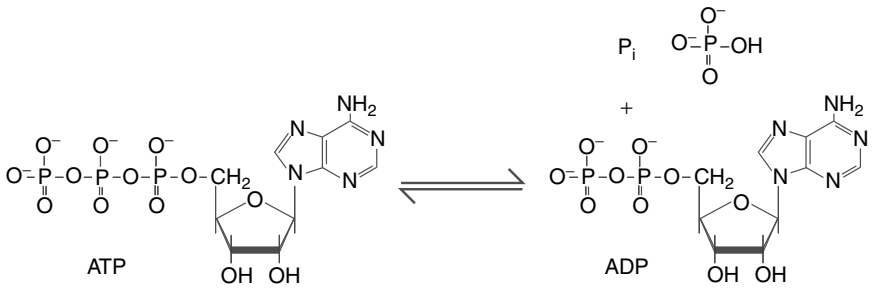
reactions (anabolic reactions and work) (Fig. 1). In principle, many different reactions could be coupled together in this manner. However, biology has evolved to exploit a few general reactions that are used to couple most catabolic and anabolic reactions, and the most important of these is the synthesis and hydrolysis of adenosine triphosphate (ATP) (Fig. 2):

$$ATP \rightleftharpoons ADP + P_i$$



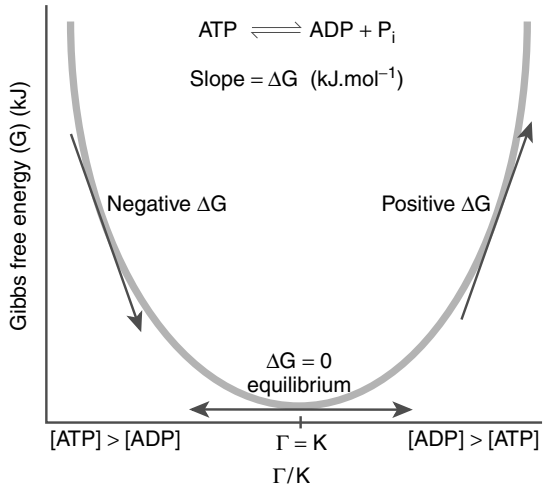


Fig. 2 Energy is stored in the displacement of ATP $\rightleftharpoons$ ADP + P_i from equilibrium. Energy from catabolic reactions is used to drive the synthesis of ATP from ADP and P_i, causing the ATP/ADP ratio to be many orders of magnitude greater than its equilibrium value (put another way, the mass action ratio (Γ) for the hydrolysis reaction is many times lower than the equilibrium constant (K)). Under these conditions, ATP hydrolysis becomes a highly favorable reaction and has a negative ΔG (indicated in the graph as the negative slope of the curve under conditions of high ATP concentration). When the ATP/ADP ratio is lower than its equilibrium value, ATP hydrolysis is not favored ($\Delta G > 0$); rather, the reverse reaction is energetically favorable. At equilibrium, the ATP/ADP ratio is equal to its equilibrium value (the mass action ratio equals the equilibrium constant), the $\Delta G = 0$, and neither the forward nor the reverse reactions are favored.

1.2 ATP Synthesis and Hydrolysis as a Coupling Reaction

The energy made available from the catabolism of food is funneled into a few forms that can be used in a wide range of anabolic and work reactions. The main reaction "chosen" by evolution for this purpose is the ADP + P_i ⇌ ATP reaction. The energetically favorable reactions of catabolism are coupled to the synthesis of ATP from adenosine diphosphate (ADP) and P_i, and, in turn, the energy released by hydrolysis of ATP to ADP is coupled to work and anabolic reactions (Figs. 1 and 2). There are a number of reasons why this reaction plays a central role in biology. The equilibrium constant of the reaction enables it to straddle both the highly exergonic catabolic reactions and the highly endergonic anabolic reactions. Furthermore, coupling requires that the reaction be easily combined with many others within the active sites of enzymes, and phosphate transfer or ATP hydrolysis can be coupled to a wide range of reactions. Finally, while the hydrolysis of ATP at the biological concentrations of ATP, ADP, and P_i must be thermodynamically favorable in order to act as an energy store, it must not occur without the action of enzymes capable of harnessing the released energy for useful functions. The phosphodiester bonds in ATP fulfill this role as they are kinetically stable *in vivo*, but the activation energy for hydrolysis of the phosphodiester bond is easily decreased by appropriate arrangements within the active sites of enzymes to stabilize the pentagonal bipyramidal transition states. For these and other reasons, the ATP ⇌ ADP + P_i reaction is central to bioenergetics.

1.3 Energy is Stored in the Displacement from Equilibrium of the ATP Hydrolysis Reaction

The ATP hydrolysis reaction (ATP ⇌ ADP + P_i) couples catabolic and anabolic reactions by storing energy in its displacement from equilibrium. As is the case for all chemical reactions, the amount of energy stored is determined by the mass action ratio (Γ; a measure of the relative concentrations of reactants and products) and its relationship to the equilibrium constant (K; a measure of the relative concentrations of reactants and products *at equilibrium*).

For ATP hydrolysis the mass action ratio is

$$\Gamma = [ADP][P_i]/[ATP]$$

The equilibrium constant is the special case of this reaction in which the reactants and products are at equilibrium ($K \sim 10^5$ M at pH 7). To see how energy is stored in this reaction, ΔG can be calculated from the following equation:

$$\Delta G = RT \ln(\Gamma/K)$$

This equation shows clearly the relationship between the displacement from equilibrium and the amount of energy stored, with $\Delta G = 0$ when the reaction is at equilibrium. This equation can be easily rearranged to give the more usual textbook presentation:

$$\Delta G = RT \ln\Gamma - RT \ln K$$

or, as $-RT \ln K$ is often written as ΔG^o,

$$\Delta G = \Delta G^o + RT \ln\Gamma$$

This equation shows that ΔG^o is merely another way of stating the equilibrium constant, and illustrates how misleading

are discussions of cellular thermodynamics based on ΔG^{o}. It also emphasizes that the relevant concentrations of the reactants and products must be used in calculating ΔG.

In vivo, catabolic reactions hold the cytoplasmic concentrations of ATP $\sim$ 5 mM and ADP $\sim$ 100 to 500 μM, corresponding to a displacement from equilibrium of 8 to 10 orders of magnitude. The role of this displacement from equilibrium in energy storage is further illustrated in Fig. 2, which shows ΔG as a function of Γ/K. The energy stored *in vivo* in this reaction is about $-50\ kJ.mol^{-1}$. Note that this does not refer to the *y*-axis scale, or the energy change that would occur if the system were able to move from the *in vivo* position to that of $K = \Gamma$. Instead, the relevant ΔG is the slope of the curve, which is about $-50\ kJ.mol^{-1}$. This is the amount of work made possible when 1 mol of ATP is hydrolyzed without affecting the overall concentrations of ATP, ADP, and P_i. Equally, the ΔG for synthesis of 1 mol of ATP under these conditions is $+50\ kJ.mol^{-1}$; the energy change is the same as for hydrolysis, but the sign is opposite. *In vivo*, other reactions are constantly maintaining a ΔG of about $-50\ kJ.mol^{-1}$ for ATP hydrolysis by synthesizing ATP through reactions that require an energy input of about $50\ kJ.mol^{-1}$.

A corollary of this continual synthesis and breakdown of ATP is that ATP molecules within the cell (5 mM; approximately 100 g in the average male human) are turned over very rapidly. Indeed, it is estimated that a resting human will hydrolyze the equivalent of his or her own body weight of ATP every day. Furthermore, the turnover of ATP is increased greatly during periods of intense activity: a marathon runner may hydrolyze up to 10 g of ATP per second. Were we to rely on our ATP stores for energy, they would run out within about 2 min. So, it is clear that ATP acts as a go-between rather than as an energy store, ferrying energy from a primary source to drive a wide range of otherwise unfavorable reactions.

2 Energy Sources that Displace the ATP Hydrolysis Reaction from Equilibrium

2.1 Carbohydrate, Fat, and Protein as Energy Sources

The energy stored in the displacement from equilibrium of the ATP $\rightleftharpoons$ ADP + P_i reaction can act only as a transient energy intermediary. Other energy sources must be used to maintain the displacement from equilibrium of this reaction as ATP is used to do work. For mammals, this energy comes from food, specifically carbohydrate, fat, and protein. In the short term, carbohydrate and fat from our last meal circulates in the bloodstream for a few hours and can be used to provide energy; however, as we do not eat continually we have to store energy within our bodies. Fat in the form of triacylglycerides in adipose tissue is the most energy-dense store ($\sim 39\ kJ.g^{-1}$) and is consequently used for long-term energy storage. Carbohydrate ($\sim 17\ kJ.g^{-1}$) in the form of liver glycogen can be broken down to maintain glucose in the blood for 12 to 24 h; in the longer term, blood glucose levels are maintained by gluconeogenesis. Dietary protein is broken down to amino acids and those not required for protein synthesis are metabolized by pathways similar to those used for carbohydrates. During extended starvation, amino acids can be released from the body's protein

to provide energy. All of these energy stores are broken down by sequential catabolic reactions that use the stored chemical potential energy to displace the ATP hydrolysis reaction from equilibrium. How these occur is considered next (Fig. 3).

2.2 Glycolysis

When glucose enters the cell, it is converted to two molecules of pyruvate by a sequence of linked enzymatic reactions termed *glycolysis*. Two reactions in this sequence, catalyzed by phosphoglycerate kinase and pyruvate kinase, are coupled to the synthesis of ATP from ADP and P_i and so contribute to the displacement from equilibrium of the ATP hydrolysis reaction (although only a fraction of the chemical potential energy stored in glucose is released at this stage). During glycolysis, electrons are removed from the carbohydrate intermediates and are transferred to the electron carrier NAD^+, reducing it to NADH (Fig. 4). However, to maintain a flux through the glycolytic pathway, it is necessary to reoxidize the NADH continually to NAD^+. In mammals, this can occur in the absence of oxygen through the reduction of pyruvate by NADH; this reaction produces lactic acid and is catalyzed by lactate dehydrogenase. In the presence of oxygen, it is possible to extract far more ATP from glucose, but, for this, both the pyruvate and the electrons from NADH must be transported into mitochondria.

2.3 Mitochondria, the TCA Cycle and β Oxidation

The mitochondrion is the organelle at the heart of energy metabolism and ATP synthesis in eukaryotic cells. Most eukaryotic cells contain hundreds of mitochondria, which are filamentous organelles comprising a matrix surrounded by an invaginated inner membrane and a semipermeable outer membrane. Mitochondria arose from free-living bacteria that set up home within the cytoplasm of the protoeukaryotic cell, a process called *endosymbiosis*. These organelles break down fats and carbohydrate-derived metabolites using oxygen to maximize the amount of energy released and then use this energy to synthesize ATP.

To extract energy from carbohydrates, the pyruvate produced by glycolysis is taken up into the mitochondrial matrix. There, the three-carbon pyruvate is converted to a two-carbon acetyl group, which is carried by Coenzyme A as acetyl CoA. Acetyl CoA then reacts with the four-carbon oxaloacetate; together they generate the six-carbon citrate. In this way, carbohydrates enter the tricarboxylic acid (TCA) cycle (Fig. 3). In the course of the TCA cycle, oxaloacetate is reformed from citrate through a series of reactions that split off CO_2 and oxidize cycle intermediates, with the concomitant reduction of the electron carriers NAD^+ and FAD to NADH and $FADH_2$, respectively (Fig. 4). A single GTP molecule is also produced by each ''rotation'' of the TCA cycle; GTP is readily converted to ATP through the action of nucleoside diphosphate kinase. The oxaloacetate is then available to accept a further acetyl group from acetyl CoA and thus keeps the TCA cycle turning. When amino acids derived from the breakdown of proteins are used as energy sources, they are broken down to derivatives that are also fed into the TCA cycle.

Mitochondria are also the site of oxidation of the fatty acids derived from triacylglyceride, the storage form of fat. Within the cytoplasm, fatty acids are first

linked to CoA to form acyl CoA and then converted to acyl carnitine. This is taken up into mitochondria through the inner membrane in exchange for carnitine. The acyl carnitine then reacts with CoA to form an acyl CoA within mitochondria. Typically, fatty acids are 16 to 18 carbons in length and within mitochondria they are broken down and oxidized by a process called *β oxidation*. During β oxidation, the acyl CoA goes through a continuous cycle of degradation and oxidation. In each cycle, two carbon units are removed from the acyl CoA to form acetyl CoA, and electrons are removed from the shortening fatty acid to reduce NAD^+ and FAD to NADH and $FADH_2$. This cycling persists until the fatty acid has been completely converted to acetyl CoA, which is then fed into the TCA cycle.

The endpoint of the metabolism of carbohydrates, fats, and protein within mitochondria is the formation of CO_2, NADH, and $FADH_2$. The CO_2 will diffuse out of the cells and be expired through the lungs; NADH and $FADH_2$ will be reoxidized. While the major function of the breakdown of fats and carbohydrates by mitochondria is to provide chemical energy to displace the ATP hydrolysis reaction from equilibrium, at this point only a fraction of the potential energy available has been used to make ATP (through glycolysis and by the formation of GTP). It is the reoxidation of NADH and $FADH_2$ that supplies the majority of the chemical potential energy for ATP synthesis. The means of coupling these two processes is discussed in the following sections.

3 Oxidation of NADH and $FADH_2$ by Mitochondria

Through the action of the TCA cycle and β oxidation within the mitochondrial matrix, there is an accumulation of electrons in the reduced carriers, NADH and $FADH_2$. The NADH pool within the matrix is soluble, and, typically, the ratio of NAD^+/NADH within mitochondria is about 5 to 10. The NADH built up in the cytoplasm by glycolysis can also be transported indirectly to the mitochondrial matrix through the malate–aspartate shuttle, or can donate electrons to the α-glycerophosphate

Fig. 3 Metabolic sources of the reducing equivalents NADH and $FADH_2$, and ATP. A small amount of NAD^+ is reduced to NADH with each round of glycolysis. This NADH can either be reoxidized to enable glycolysis to continue, or imported indirectly into mitochondria where it donates electrons to the mitochondrial respiratory chain. Pyruvate, the product of glycolysis, is transported to mitochondria where it is converted to acetyl CoA and enters the TCA cycle. The sequential oxidation of citrate enables the reduction of NAD^+ and FAD to NADH and $FADH_2$. Each ''rotation'' of the TCA cycle also produces a single GTP molecule (energetically equivalent to ATP). Triacylglyceride lipids are broken down into glycerol and fatty acids. Glycerol feeds into glycolysis, while fatty acids are transported to mitochondria and undergo multiple cycles of β oxidation, with each cycle yielding acetyl CoA (which feeds into the TCA cycle) and reducing NAD^+ and FAD to NADH and $FADH_2$. Proteins are metabolized through breakdown into amino acid monomers and the subsequent conversion of amino acids to pyruvate, acetyl CoA or TCA cycle intermediates. Black circles indicate either direct transport into mitochondria (e.g. the pyruvate transporter), or net transport through several molecular interconversions (e.g. the malate–aspartate shuttle for the ''transport'' of NADH). In summary, the catabolic reactions of metabolism act to reduce the electron carriers NAD^+ and FAD to NADH and $FADH_2$, and produce a small amount of ATP.

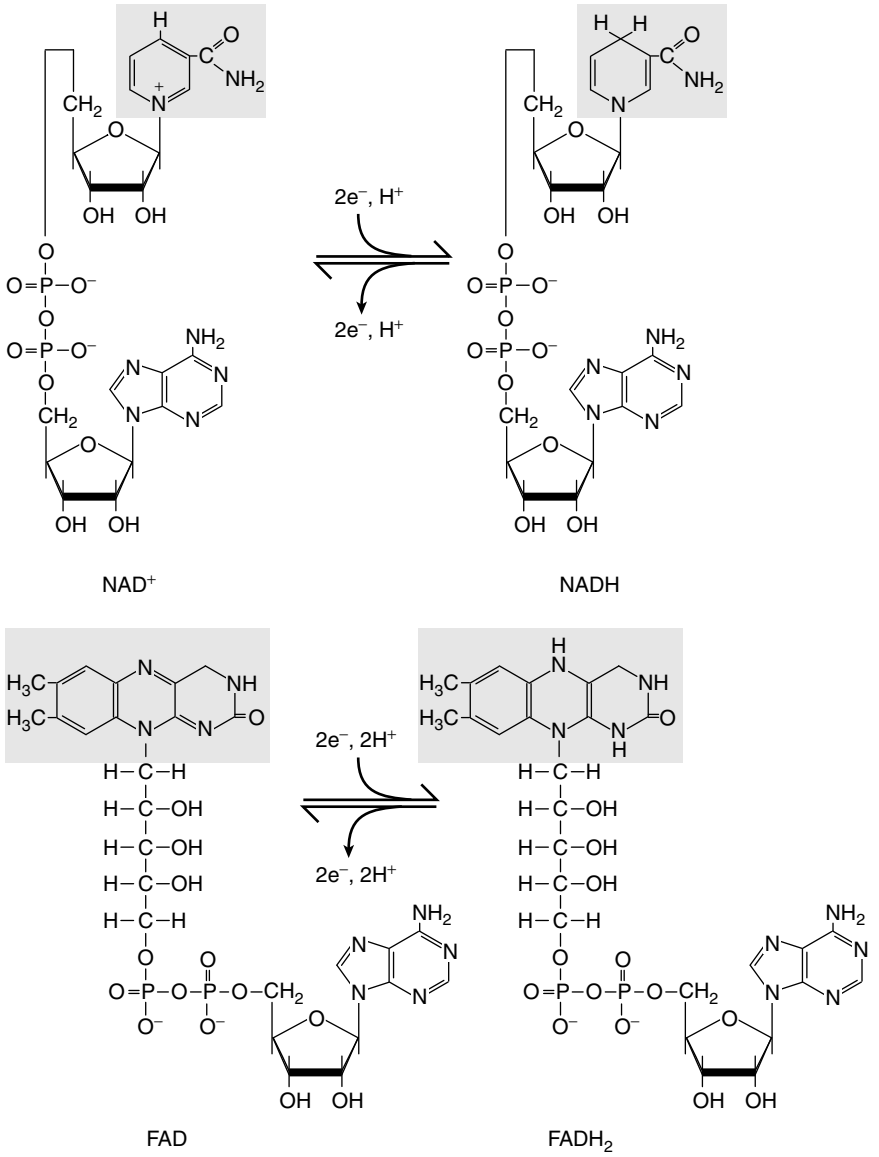

Fig. 4 Reduction of the electron carriers NAD^+ and FAD to their reduced forms NADH and $FADH_2$. Both carriers accept two electrons in conversion to the reduced form.

dehydrogenase on the outer surface of the mitochondrial inner membrane (Fig. 5). In contrast, the $FADH_2$ groups are not free in solution but are bound within the active sites of a number of different proteins, such as succinate dehydrogenase (for electrons derived from the TCA cycle), or on the electron transfer flavoprotein (ETF) (for electrons derived from β oxidation).

The reduction potential (E_h) of the NAD^+/NADH couple can be derived from the midpoint potential of the couple (E_m, ~ -320 mV) as follows:

$$E_h = E_m + \frac{RT}{2F} \ln\left(\frac{[NAD^+]}{[NADH]}\right)$$

$$E_h \sim -290 \text{ mV}$$

As the energy stored in this redox couple will be released by the reduction of oxygen, it should be compared with the E_h value for the O_2/water couple, which is about +790 mV for air-saturated water. This gives a ΔE_h of 1080 mV for the oxidation of NADH by O_2, corresponding to a ΔG of -208 kJ.mol^{-1}. In comparison, $FADH_2$ passes electrons directly to the ubiquinone/ubiquinol couple, which has a somewhat higher E_h ($\sim +10$ mV) than NADH, and thus a lower ΔE_h ($\sim$780 mV) and less negative ΔG (~ -150 kJ.mol^{-1}) for electron transfer to O_2.

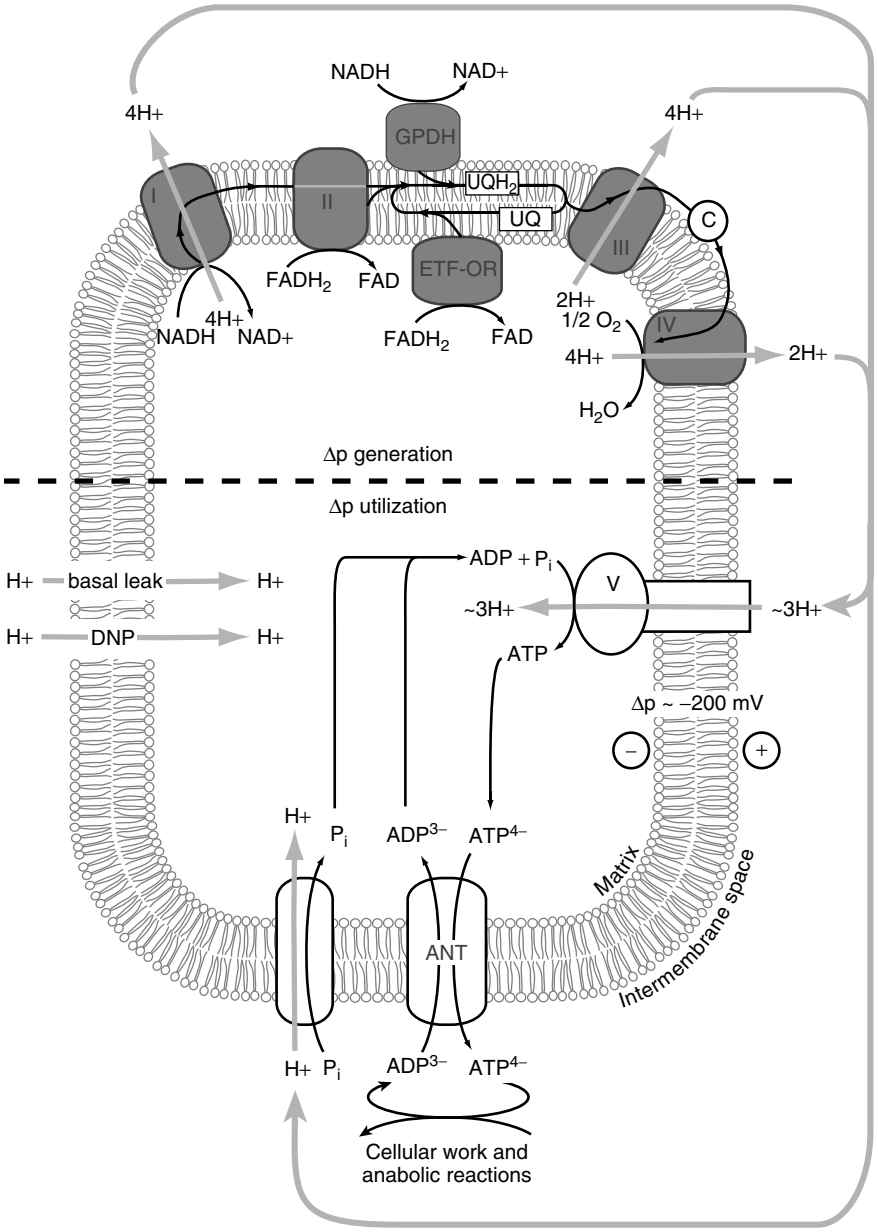
The redox energy stored by NADH and $FADH_2$ is ultimately released on reaction with oxygen. However, were this to be done by direct reaction with O_2, the energy would be dissipated uncontrollably as heat and could not be harnessed for ATP synthesis. Instead, the release of the redox potential energy stored in NADH and $FADH_2$ is controlled by the action of the mitochondrial respiratory chain.

3.1 The Mitochondrial Respiratory Chain

The respiratory chain is a sequence of electron carriers embedded within the mitochondrial inner membrane that catalyzes electron movement from NADH and $FADH_2$ to oxygen (Fig. 5). The first component of the respiratory chain is complex I, a massive membrane protein complex of about 980 kDa. This protein takes electrons from NADH and passes them to a flavin mononucleotide within complex I. From there, the electrons pass through a series of iron–sulfur centers and are then used to reduce ubiquinone to ubiquinol; these are the two redox forms of Coenzyme Q (CoQ), a small, mobile electron carrier within the mitochondrial inner membrane, which is not a protein but a hydrophobic organic molecule.

A number of other respiratory complexes also pass electrons to CoQ. Complex II, or succinate dehydrogenase, catalyzes the oxidation of succinate to fumarate in the TCA cycle. The electrons initially reduce a bound FAD within complex II; the resultant $FADH_2$ passes the electrons through a series of iron–sulfur centers to the CoQ binding site within the membrane where they reduce ubiquinone to ubiquinol. α-Glycerophosphate dehydrogenase (GPDH) is an enzyme on the outer surface of the mitochondrial inner membrane that is expressed in some tissues. This enzyme oxidizes α-glycerophosphate to dihydroxyacetone phosphate and uses the electrons to reduce a bound FAD within the enzyme, which then reduces ubiquinone to ubiquinol. The oxidation of fatty acids by β oxidation leads to the reduction of an FAD in a small mobile protein within the mitochondrial matrix called *electron transfer flavoprotein* (ETF). This electron carrier is reoxidized by the respiratory chain through an inner membrane protein called *ETF–ubiquinone oxidoreductase* (ETF-OR). This enzyme reduces an internal FAD and subsequently reduces ubiquinone to ubiquinol, possibly *via* an iron–sulfur center. Therefore, these, and other, enzymes catalyze electron flow into the CoQ pool. *In vivo*, the CoQ pool is generally about 70 to 80% in the reduced (ubiquinol) form.

The fate of ubiquinol is oxidation by complex III (also known as the cytochrome bc_1 complex), the next component of the respiratory chain. Complex III takes two electrons from the ubiquinol of the CoQ pool and passes them through a branching pathway where one electron goes through the two b-type cytochromes before being passed back to reduce ubiquinone. The other electron reduces an iron–sulfur



center, called the *Rieske iron-sulfur center*, and from there reduces a cytochrome c_1. This cytochrome is the last electron carrier in the complex and passes its electron to cytochrome c, a small protein that acts as a mobile electron carrier on the cytoplasmic surface of the mitochondrial inner membrane. The enzymes sulfite oxidase and NADH-cytochrome b_5 reductase (via cytochrome b_5) can also pass electrons to cytochrome c, but the flux through these reactions *in vivo* is thought to be small.

Cytochrome c carries electrons to complex IV (or cytochrome oxidase), the final stage of their journey toward oxygen. It is at cytochrome oxidase that about 95% of the oxygen we breathe is reduced to water. The electron from cytochrome c is initially passed to the heme *a* site within cytochrome oxidase and then to the Cu_a site. From there, the electrons pass to the heme a_3 site, which also contains the Cu_b center. Here the terminal electron acceptor of the respiratory chain, O_2, binds and is reduced to water.

So far, we have outlined the pathway taken by electrons as they move through the respiratory chain. In the next section, the mechanism of coupling this movement to ATP synthesis is explained.

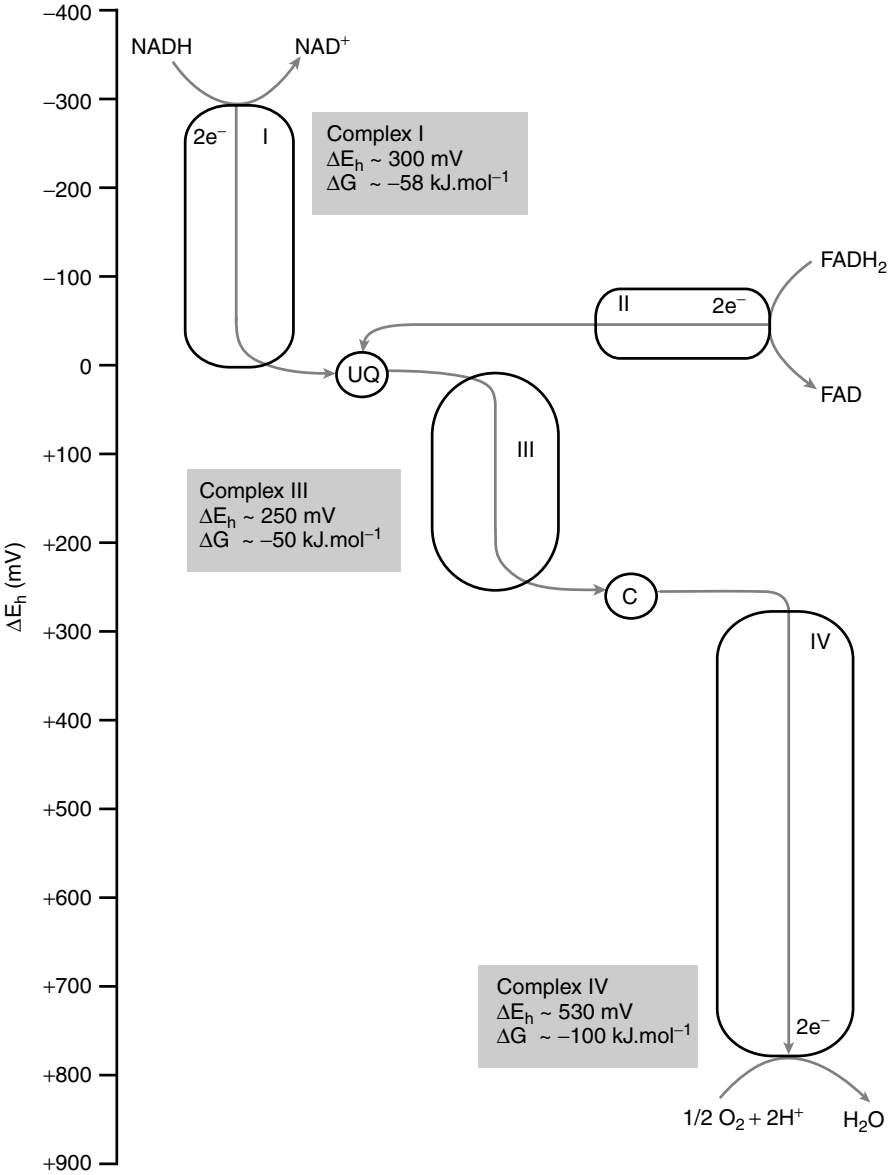
3.2 Energy Storage by the Protonmotive Force (Δp)

The respiratory chain provides a complex pathway for the gradual movement of electrons from the low potential of NADH (~ -290 mV) to the high potential of oxygen ($\sim +790$ mV). This pathway enables the gradual release of potential energy and is best illustrated by Fig. 6, which shows the gradual increase in reduction potential (E_h) as electrons pass through the respiratory chain. Three significant changes in E_h are apparent within the respiratory chain, at complexes I, III, and IV; the large increases in E_h – which signify large drops in the potential energy of the electrons – suggest that at these three points the redox energy may be conserved as an intermediate that can be used to make ATP.

The mechanism of coupling of electron transport and ATP synthesis was one of the major challenges to biochemistry

Fig. 5 NADH and $FADH_2$ are oxidized by the mitochondrial respiratory chain, giving rise to the protonmotive force and ATP synthesis. NADH and $FADH_2$ donate electrons to the respiratory chain through a number of inner membrane proteins and multiprotein complexes: complex I (mitochondrial NADH), α-glycerophosphate dehydrogenase (GPDH; cytosolic NADH), complex II (TCA cycle-derived $FADH_2$) and electron transfer flavoprotein–ubiquinone oxidoreductase (ETF-OR; β oxidation-derived $FADH_2$). Each of these proximal electron acceptors feeds electrons to CoQ, reducing ubiquinone (UQ) to ubiquinol (UQH_2). Electrons are subsequently passed through complex III, cytochrome c, and complex IV, finally reducing O_2 to H_2O. Complexes I, III, and IV all derive sufficient energy from the drop in redox potential of electrons to catalyze the pumping of protons out of the matrix and into the cytoplasm. This generates a protonmotive force (Δp) across the mitochondrial inner membrane. Driven by Δp, protons flow back into the matrix through the ATP synthase (complex V), catalyzing the formation of ATP from ADP and P_i. Some protons can also return to the matrix by mechanisms that do not involve passage through the ATP synthase, such as the basal leak through the inner membrane in all mitochondria, or via uncouplers such as 2,4-dinitrophenol (DNP) that render the inner membrane permeable to protons. Newly synthesized ATP^{4-} is transported out of the mitochondria and into the cytosol by exchange with ADP^{3-}, which in turn is converted to ATP. The P_i required for ATP synthesis is transported into the matrix in symport with a proton.

in the 1970s and early 1980s. The two processes are now known to be linked by ''chemiosmotic coupling,'' a concept developed by Peter Mitchell in the early 1960s and established over the subsequent two decades. The energy available as the electrons pass through complexes I, III, and IV is used to pump protons out of the matrix across the mitochondrial inner membrane. For every pair of electrons that passes through the respiratory chain, 4 H^+ are translocated at complex I, 4 H^+



at complex III, and 2 H^+ at complex IV (although the movement of electrons with respect to the membrane at complexes III and IV means that the charges translocated by complexes I, III, and IV are 4, 2, and 4, respectively). The reduction of O_2 to water requires 4 e^- , so a pair of electrons corresponds to the reduction of a single O atom. As the two electrons go through the respiratory chain from NADH, 10 protons and charges are pumped across the inner membrane, while for electrons coming from $FADH_2$, six protons and charges are translocated.

Proton pumping builds up a charge gradient, or membrane potential, across the inner membrane ($\Delta\psi$ in mV, negative inside) (Fig. 5). In addition, proton translocation also leads to a proton concentration gradient across the inner membrane, which is usually expressed as a pH gradient (ΔpH, basic inside). Both the membrane potential and the pH gradient raise the potential energy of protons outside the mitochondrial inner membrane relative to those inside. The contribution of the two components to this potential energy difference is conveniently expressed as the protonmotive force. For this, the pH gradient is multiplied by $-2.303RT/F$ to express its value in mV; this can be added to the membrane potential to give the protonmotive force (Δp):

$$\Delta p = \Delta\psi - (2.303RT/F)\Delta pH$$

The advantage of this formulation is that the relative contributions of $\Delta\psi$ and ΔpH are clear. In isolated mitochondria, the maximum $\Delta\psi$ is about 170 to 190 mV and the pH gradient can be up to -0.5 to -1 pH unit (basic inside, hence the negative sign in the equation). At 37 °C, $2.303RT/F = 61$ mV, so the maximum Δp is typically around 180 to 200 mV. In cells, the average values tend to be lower because of the utilization of Δp to synthesize ATP, as well as limiting electron and O_2 supply.

To maintain the Δp across the mitochondrial inner membrane, the membrane has to be topologically intact and the phospholipid bilayer must be relatively impermeant to protons. A further implication of the closed membrane is that mechanisms must exist for the transport of polar metabolites across the membrane, such as pyruvate, ATP, ADP, and P_i, among many others. As this movement has to occur without dissipating the Δp, the metabolite carriers in the mitochondrial inner membrane must be able to catalyze transport without rendering the membrane permeable to protons. In summary, the redox energy stored by NADH

Fig. 6 Sequential increases in redox potential (E_h) of respiratory chain components are coupled to proton pumping. NADH, a major electron donor to the mitochondrial respiratory chain, has a low E_h (~ -290 mV) under conditions found in the matrix. After oxidation of NADH by complex I, electrons are passed through a series of electron carriers in the complex (not shown) before reducing the mobile electron carrier ubiquinone ($E_h \sim +10$ mV). The large increase in E_h of respiratory components between NADH and ubiquinone – and hence the drop in redox potential energy of the transported electrons – provides sufficient energy for translocation of $4H^+$ (per $2e^-$) by complex I into the cytosol. Similarly, increases in E_h between ubiquinol and oxidized cytochrome c ($E_h \sim +260$ mV), and between reduced cytochrome c and O_2 ($E_h \sim +790$ mV), provide sufficient energy for proton translocation at complexes III ($4H^+$) and IV ($2H^+$) , respectively. ΔE_h values shown for complexes I, III, and IV have been calculated from the increases in redox potential between NADH and ubiquinone, ubiquinol and oxidized cytochrome c, and reduced cytochrome c and O_2, respectively.

and $FADH_2$ is conserved as a protonmotive force that comprises a $\Delta\psi$ and a ΔpH across the mitochondrial inner membrane. This protonmotive force can now be used for the synthesis and transport of ATP.

3.3 The Protonmotive Force Drives ATP Synthesis and Transport

The energy stored in Δp is used to drive the synthesis of ATP through the action of the ATP synthase. This protein complex is also found in the mitochondrial inner membrane and catalyzes the movement of protons down their proton electrochemical gradient from the cytoplasm, back into the mitochondrial matrix. The drop in potential energy as the protons pass through the complex provides the energy for ATP synthesis by the synthase. This remarkable enzyme has a hydrophobic domain (the F_O domain) embedded in the lipid bilayer, which facilitates proton movement through the lipid bilayer, and a connected F_1 component in the mitochondrial matrix where the ATP is made (Fig. 7). The F_O subcomplex comprises a ring of 10 to 14 identical hydrophobic proteins called *subunit c*. This ring is attached to a stator arm that links together the F_O and F_1 subcomplexes. As a proton passes through the membrane, it forces the rotation of F_O relative to the stator arm, with the concomitant rotation of a second protein subunit, γ. The γ subunit is attached at its base to F_O; the remainder of the protein is inserted into the center of the F_1 complex, which comprises 3 α and 3 β subunits arranged alternately like the segments of an orange. This assembly of 3 α and 3 β subunits is held in place by the stator arm, so proton movement drives the rotation of F_O and the γ subunit relative to F_1. The rotation of the γ subunit against the α and β subunits forces the three catalytic sites at the interfaces of the α and β subunits to change shape, with each site switching between three conformations that alternately bind ADP and P_i, synthesize ATP, and finally release ATP. The Δp is used to drive the rotation of the γ subunit relative to the α and β subunits at about 50 to 100 Hz *in vivo*; thus, Δp is converted to mechanical energy and then back to chemical energy in the displacement from equilibrium of the ATP hydrolysis reaction. Each complete rotation of the γ subunit within the ATP synthase enables the synthesis of three ATP molecules. This is associated with the complete rotation of F_O. It is likely that the number of protons translocated for each complete F_O rotation equals the number of c subunits; since there are thought to be at least 10 subunit c components in mammals, this suggests that 3.3 or more H^+ are transported per ATP synthesized. However, direct measurement of the number of H^+ translocated per ATP synthesized puts the ratio at about 3.

The ATP synthase makes ATP in the mitochondrial matrix, but, as most ATP is consumed in the cytoplasm, ATP must be exported from the mitochondrion. In addition, P_i and ADP must be imported into mitochondria from the cytoplasm. Much of the anion transport across the mitochondrial inner membrane is accomplished by a family of carriers of about 30 to 35 kDa. Among these are the adenine nucleotide translocator (ANT) and the phosphate carrier (Fig. 5). The ANT catalyzes exchange of ATP^{4-} in the mitochondrial matrix with ADP^{3-} in the cytoplasm, hence transport involves the net movement of a positive charge into the mitochondrion, and ATP export and ADP

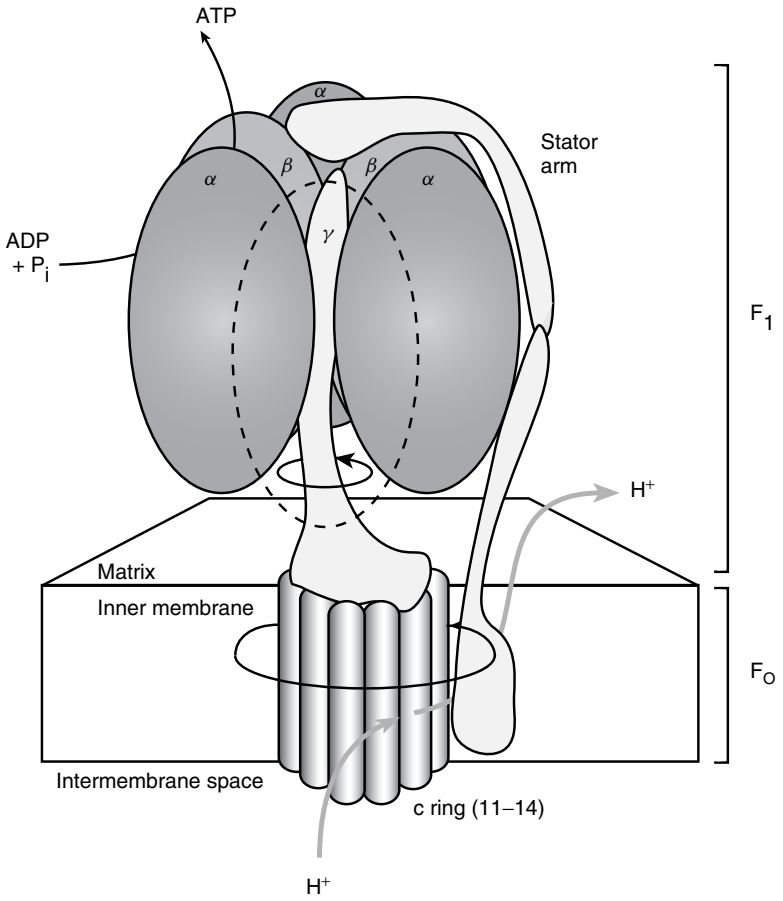


Fig. 7 The mitochondrial ATP synthase. To synthesize ATP, the ATP synthase harnesses the energy stored in the Δp across the mitochondrial inner membrane. Protons move down their electrochemical gradient from the intermembrane space via the ring of c subunits (F_O subcomplex) embedded in the membrane, catalyzing the rotation of both the F_O subcomplex and the neighboring γ subunit (part of the F_1 subcomplex). Rotation of the γ subunit relative to the static $\alpha_3\beta_3$ subunits (held in place by the stator arm) alters the shape of the three catalytic sites at interfaces between α and β subunits, promoting sequential ADP and P_i binding, ATP synthesis, and finally the release of ATP from the enzyme.

import is driven by the membrane potential component of Δp. A consequence of this is a higher ATP/ADP ratio in the cytoplasm than in the mitochondrial matrix. So, the displacement from equilibrium of the ATP hydrolysis reaction is driven by Δp acting through both the ATP synthase and the ANT. The phosphate carrier takes up the P_i required for ATP synthesis in electroneutral symport with a proton; hence, P_i uptake is driven by the ΔpH component of Δp. In sum, the import of ADP and P_i and the export of ATP is associated with the movement

of one proton through the mitochondrial inner membrane. So, if it takes approximately three protons to synthesize an ATP molecule in the matrix, it takes about four protons to synthesize ATP in the cytoplasm.

A final consideration is the number of oxygen atoms that must be consumed to synthesize an ATP molecule and export it to the cytoplasm. As the oxidation of NADH or $FADH_2$ pumps 10 and 6 protons respectively, the theoretical P/O ratios are 10/4 for NADH and 6/4 for $FADH_2$. The true values will be less because of inefficiencies such as leakage of protons through the mitochondrial inner membrane.

3.4 Respiratory Control and Uncoupling

As mitochondria make ATP, they consume Δp, enabling them to sense and respond to the rate of ATP consumption. ATP hydrolysis increases the ADP concentration, thereby elevating the rate of ATP synthesis. Greater ATP synthase activity involves the consumption of Δp, which is then matched by a rise in respiration rate, as the respiratory chain responds to the decreased Δp by increasing electron flow and proton pumping to maintain Δp. This phenomenon is known as *respiratory control* and enables mitochondria to match ATP synthesis to ATP consumption, maintaining the displacement from equilibrium of the ATP hydrolysis reaction under conditions of variable ATP demands.

The link between respiration rate and Δp is also indicated by the phenomenon of uncoupling. To maintain Δp, the mitochondrial inner membrane is relatively impermeable to protons. Uncouplers counteract this by making the inner membrane permeable to protons. Uncouplers are typically lipophilic weak acids in which the conjugate base is also lipophilic. An example is 2,4-dinitrophenol (DNP; Fig. 5) where the charge on the phenolate anion is delocalized and, consequently, both the anion and its conjugate acid are lipid soluble. This enables DNP to partition into the phospholipid bilayer of the mitochondrial inner membrane, where it can shuttle across the membrane, picking up a proton on the intermembrane space side and depositing it in the matrix. Thus, uncouplers catalyze proton movement through the lipid bilayer; in the presence of an uncoupler, the mitochondrial inner membrane is effectively permeant to protons and consequently cannot maintain a Δp. In response, the mitochondria respire rapidly to pump out protons in a vain attempt to maintain a Δp, which is instead rapidly dissipated as heat (Fig. 8).

3.5 Alternative Uses of the Protonmotive Force

While the principal function of Δp is the synthesis and export of ATP from the mitochondrion, there are other processes that exploit Δp to carry out work. These include metabolite transporters that catalyze movement across the mitochondrial inner membrane by coupling to charge or proton translocation (analogous to ADP/ATP antiport and P_i transport). The movement of calcium across the mitochondrial inner membrane is also driven by Δp. There is a calcium uniporter in the mitochondrial inner membrane that enables calcium uptake into mitochondria. As only the calcium dication is translocated, uptake is driven solely by the membrane potential. In addition, there is a separate

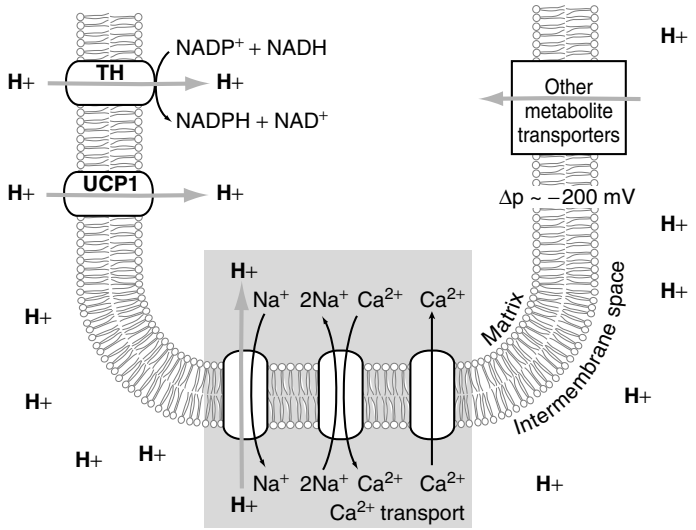

Fig. 8 Alternative fates of Δp. While the major function of the Δp is to generate ATP, proton movement down the electrochemical potential gradient across the mitochondrial inner membrane can be coupled to other activities. Such Δp-dependent processes include the action of the transhydrogenase (TH), which exploits Δp to drive reduction of $NADP^+$ to NADPH, at the expense of NADH; thermogenesis in brown adipose tissue by uncoupling protein 1 (UCP1), which dissipates the Δp as heat by increasing the proton permeance of the inner membrane; the activity of an Na^+-H^+ antiporter and Ca^{2+} uniporter, which (in concert with a $2Na^+/Ca^{2+}$ antiporter) exploit the ΔpH and $\Delta\psi$ components of the Δp, respectively, to catalyze mitochondrial uptake of calcium ions; and the transport of a number of other metabolites.

exchange activity involving electroneutral exchange of Ca^{2+} for $2H^+$ or $2Na^+$. In conjunction with the Ca^{2+} uniporter, this exchange can lead to the continual cycling of calcium across the mitochondrial inner membrane as cytosolic calcium increases. The overall effect is that increased cytoplasmic calcium concentration leads to a proportionate increase in calcium concentration in the mitochondrial matrix. As changes in cytosolic calcium are important signals that activate various aspects of metabolism, this mechanism enables such signals to be relayed to the mitochondrial matrix. The changes in matrix calcium activate dehydrogenases, thereby increasing electron supply to the respiratory chain and elevating ATP synthesis. The reason for this is thought to be that calcium signals are often associated with increased ATP turnover; Δp-dependent Ca^{2+} uptake enables mitochondria to upregulate ATP synthesis to match this increased demand.

A further use of Δp is in thermogenesis by brown adipose tissue. Under certain conditions, mitochondria can become uncoupled; that is, the energy stored in Δp can be dissipated as heat by providing a pathway for protons to flow back through the inner membrane to the matrix without carrying out work. Certain

molecules, such as DNP, can act as uncouplers and dissipate Δp as heat (Fig. 5). Indeed, historically, DNP was used as a slimming agent as it led to the rapid breakdown of fat stores. Physiologically regulated uncoupling is used by mitochondria in brown adipose tissue mitochondria to generate heat. Mitochondria in brown adipose tissue contain uncoupling protein 1 (UCP1), which catalyzes proton movement through the mitochondrial inner membrane. When this protein is activated, it partially uncouples mitochondria, increasing the rate of respiration such that the fat stored in brown adipose tissue is broken down and oxidized by the mitochondria. However, instead of the energy in Δp being used to make ATP, it is instead dissipated as heat. This activity enables brown adipose tissue to be a site of nonshivering thermogenesis in neonates and in small mammals exposed to the cold.

A final example of the use of Δp is the transhydrogenase (TH) enzyme in the mitochondrial inner membrane. Within the mitochondrial matrix, the $NADH/NAD^+$ ratio is about 0.1 to 0.2, while that of the $NADPH/NADP^+$ couple is approximately 99% reduced. This is thought to be because NADPH is required to maintain the mitochondrial glutathione pool and thioredoxin in a reduced state, through NADPH-dependent glutathione reductase and thioredoxin reductase. A reduced glutathione pool and reduced thioredoxin are important in protecting mitochondria from oxidative damage. One of the ways the high $NADPH/NADP^+$ ratio is maintained is through the transhydrogenase, which couples proton movement down the Δp gradient to drive electrons from NADH to $NADP^+$ and thus maintains the disparity in redox states.

4 Overview of the Metabolic Basis of Cellular Energetics

A central feature of cellular bioenergetics is the displacement from equilibrium of the ATP hydrolysis reaction. This displacement is at the heart of metabolism where it acts as a coupling reaction between catabolism and anabolic or work reactions. While there is continual turnover of ATP, the energy stored in this displacement from equilibrium is usually held at about $-50\ kJ.mol^{-1}$ through the expenditure of energy from fat, carbohydrate, or protein. As these molecules are broken down, the chemical energy is converted to redox potential energy in the reduced electron carriers NADH and $FADH_2$. This redox potential energy is gradually released as electrons pass through the mitochondrial respiratory chain and is conserved at three regions in the respiratory chain by pumping protons across the mitochondrial inner membrane. This builds up a Δp that is then used to drive the synthesis of ATP in the mitochondrion and its subsequent transport to the cytosol. Thus, there is a linked series of energy conversions, from chemical energy to redox energy and protonmotive force, followed by a return to chemical energy, which is stored in the displacement from equilibrium of the ATP hydrolysis reaction. These energy interconversions allow ATP to drive the many otherwise unfavorable reactions that are necessary for life.

Keywords

Chromatography
A range of methods designed to separate the molecular components of a complex mixture on the basis of their physical properties.

Mass Spectrometry
An analytical chemistry technique that can be used to identify molecules by fragmenting them into ions, which are then separated on the basis of mass.

Nuclear Magnetic Resonance
The context-dependent resonance of various atomic nuclei (such as the hydrogen nucleus) when placed in a magnetic field, which can be used to obtain structural information about the molecular components of a solution.

Regression Modeling
Mathematical methods designed to predict one (or more) variables from the values of many other measured variables.

Metabonomics is the study of systemic biochemical profiles and regulation of function in whole organisms by analyzing biofluids and tissues. Like genomics (the study of the complete repertoire of genes in an organism) and proteomics (the study of the protein complement of a tissue or cell), metabonomics can provide a holistic overview of the current physiological status of an organism, and its response to external stressors. Here we review the technological approaches to generating metabolic profiles, highlighting the advantages and disadvantages of each methodology, as well as the various strategies for extracting useful conclusions from the very large datasets that can be generated by such profiling. Metabonomics can be applied to a wide range of biological applications, including predictive toxicology, probing the physiology of disease both in animal models and in man, and to make clinically useful diagnoses of disease. With examples of each of these applications, we illustrate the potential of metabonomics to contribute to our understanding of complex biological systems in a post-genomic era where we understand many of the components of living systems, but few of their dynamic interactions.

1 What is Metabonomics?

The suffix ''omics'' is now routinely applied in many fields to the holistic study of an entire system, as opposed to a reductionist description of each of its parts independently. Thus, metabonomics is the name given to the holistic study of metabolic systems in living organisms. In principle, a metabolic profile is therefore a simple list of all the low molecular weight metabolites (such as sugars, amino acids, and lipids) present in a biological system, together with the concentration of each metabolite present (the generation of such profiles is one of the definitions in use for metab*o*lomics). Clearly, such a profile is analogous to a genomic profile (a list of all the genes composing an organism, perhaps with their levels of expression also) or a proteomic profile (a list of the proteins in an organism).

Like genomics and proteomics, however, metabo*n*omics is also much more than a simple list. The metabolic profile of a particular biological sample is just a snapshot of a complex, dynamic network that reflects the physiological activity of the organism. Enzymes are rapidly interconverting metabolites; new compounds are being absorbed from the environment; waste products are being excreted. The science of metabonomics, therefore, is not only about capturing metabolic profiles (described in Sect. 2 below) but also about extracting an understanding of the underlying biological system from the resulting dataset (described in Sect. 3). In particular, metabonomics is a global metabolic regulation approach based on understanding complex system behavior, designed to reveal the response of an organism to an external stressor or stimulus.

The relationship between metabonomics and other systems biology disciplines is illustrated in Fig. 1. Genetic information (coupled with the pre-existing levels of various other proteins) is the major determinant of the mRNA (or transcriptomic) profile, which in turn is a key determinant of the proteomic profile. Proteins (in the form of enzymes) are an important determinant of the metabolic profile, which, in turn, feeds back to modulate gene expression patterns. This ''homeostatic loop'' is then modulated by external inputs from the environment. The major input of low molecular weight compounds from the diet can have a significant effect on the metabonomic profile, which subsequently affects the gene expression and protein profiles of the organism. Other environmental factors can also affect the metabolic profile (for example, the amount of light determines the rate of vitamin D formation), as well as directly altering gene expression (the amount of exercise modulates skeletal muscle gene expression and ultimately protein content). This position at the interface between genetic and environmental determinants makes metabolic profiling a uniquely powerful tool for probing the dynamic physiological status of an organism.

Compared with genomic and proteomic profiles, the metabonomic profile is also more dynamic, reflecting the current physiological status of the organism as well as its future behavior. Polymorphisms, in particular genes (a component of the genomic profile), may allow the risk of developing a disease to be estimated, but they cannot determine whether the organism is suffering from that disease at a given point in time.

To properly understand the metabolic network of a multicellular organism would require continuous measurement of the

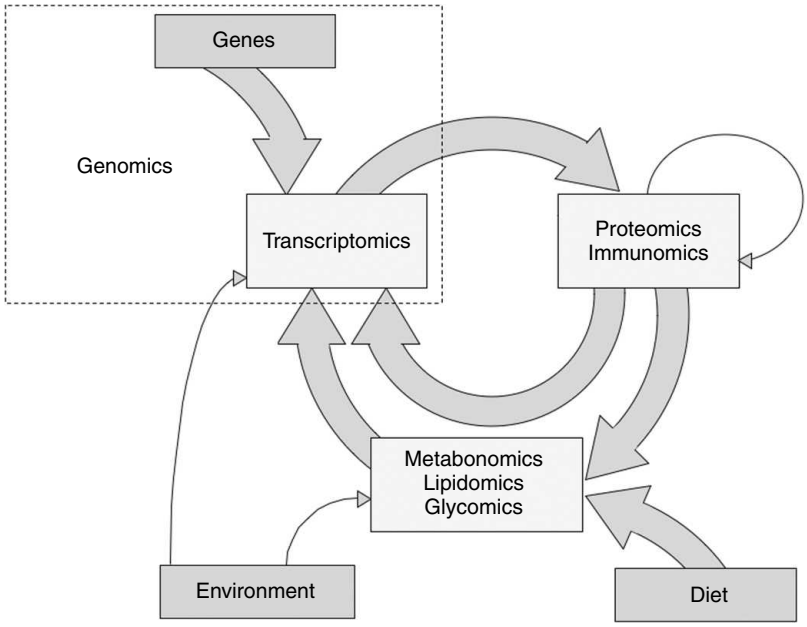

Fig. 1 Relationship between the ''omics.'' Much of the variation in protein levels (measured in proteomics) is due to variations in the expression of the mRNA encoding that protein (measured in transcriptomics, a subset of genomics). In turn, the variation in the levels of metabolites (measured in metabonomics) is determined by the levels of various enzymes (proteins). Metabolites can then feedback and regulate gene expression patterns, closing a ''homeostatic loop.'' The environment interacts with this homeostatic loop primarily through the influence of diet on the metabolic profile, although other environmental factors can also have a direct effect on both metabolism and gene expression (for example, exposure to UV light directly affects vitamin D3 levels, and exercise can affect gene expression patterns).

levels of all the metabolites present in all of the cells and tissues that compose the organism. Such an ''ideal'' metabolic profile is unlikely to be practicable attainable (at least in the near future). As a result, practical metabonomics involves selection of both a sample of the whole organism (for example, a blood specimen) and a time point (or series of time points) at which to make the observations. Clearly, the extent to which one can hope to understand the metabolism of the organism as a whole from a (potentially poorly representative) sample is unclear and care should be taken in drawing broad conclusions from limited measurements. Similarly, available analytical chemistry techniques (such as spectroscopy or chromatography) do not allow accurate measurements of the levels of every low molecular weight compound present in a given biological specimen. These practical limitations are illustrated in Fig. 2.

Even with the current practical limitations, metabonomics is a powerful new tool for studying complex biological systems. It has already been used successfully to monitor the physiological response to xenobiotics (such as new pharmaceuticals under development), and its use in

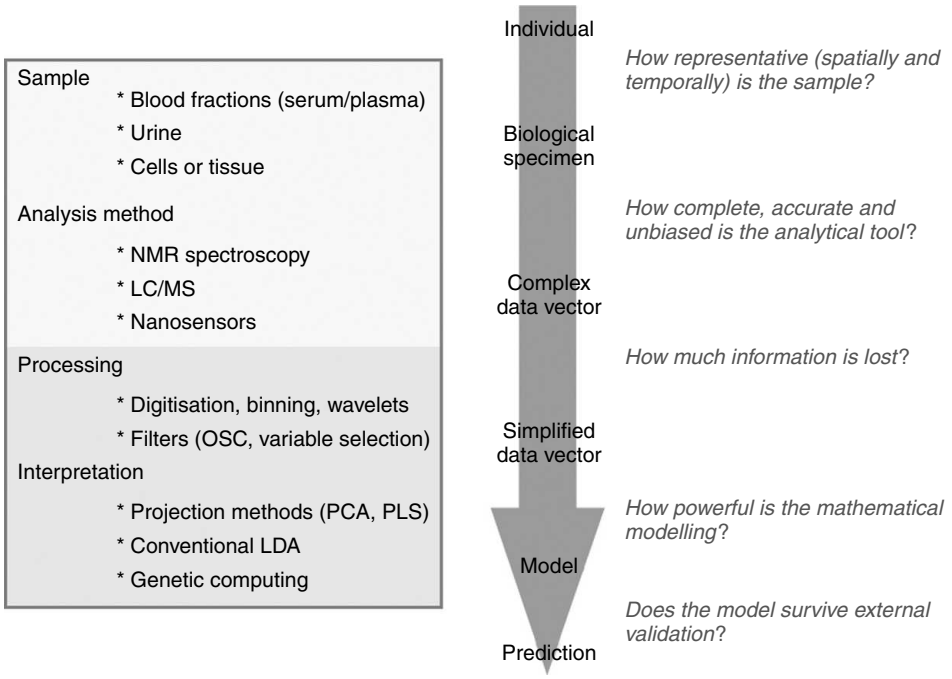

Fig. 2 A generic ''omics'' experiment. The aim of ''omics'' biology is to make measurements on individuals and then deduce predictive rules about the organism. In order to go from individual observations to a prediction, various steps must be followed: a sample must be taken on which many measurements are made to generate a complex data vector. Various mathematical modeling tools are then used to build a regression model which can be used to make a prediction that can be validated. Examples of each step in a typical metabonomics experiment are shown in the left panel. Various assumptions made at each step are listed in the right panel.

toxicology is increasing. Metabonomics can also be used to diagnose the presence of diseases, both for those where in-born errors of metabolism are responsible for the symptoms, and also in diseases where metabolic disregulation is less obviously involved in the pathogenesis of the disease. Using a metabolic profile to diagnose disease is not just useful in the clinic: it can also provide important new information about the physiological processes that are misregulated in the disease, which might ultimately assist in the search for new treatments.

The ''homeostatic loop'' illustrated in Fig. 1 also emphasizes the importance of integrating the genetic, protein, and metabolic profiles if we are to maximize our understanding of the organism. The boundaries between the ''omics'' represent technical limits in our methodologies for making measurements rather than being any useful dividing line between the applications of the information that has been generated. Fortunately, the profiles generated can be merged (at least in principle, although the bioinformatics challenges in doing so are significant) yielding a composite

(or ''multi-omics'') profile of the organism. Any question partially addressed by the separate genomic, proteomic, and metabonomic profiles will likely be more fully answered through the careful construction and analysis of such ''multi-omics'' profiles.

2 Methods for Generating a Metabonomic Profile

2.1 Criteria for Judging Metabonomic Profiling Methods

A range of different analytical chemistry approaches have been used to generate metabonomic profiles. Unfortunately, none of the profiles generated even approximate to the ''ideal'' profile, and it is necessary to make an informed choice of analytical tool depending on various trade offs. There are three important criteria that contribute to the ''ideal'' profile:

1. *Completeness*. If we assume that the ''ideal'' profile consists of a list of all the different low molecular weight compounds present in a biological sample, then any profiling method can be judged on the fraction of all the metabolites present that contribute to the profile. In absolute terms, this can be difficult to assess, since without a ''gold standard'' complete profile it is impossible to know what components have been missed. In practice, however, applying multiple analytical approaches to the same sample soon throws up examples of components missed by the other techniques.

Two factors contribute to the completeness of a profile. Firstly, the general sensitivity limit of the technique sets the threshold below which no components are detected. While an ''ideal'' profile would include even components present as just a single molecule, practicality suggests that components present at such low levels are unlikely to have a biologically significant effect, and that a profile with sensitivity threshold in the pM or nM range would be adequate for all but the most demanding applications. Unfortunately, several techniques are more insensitive still, and will miss components that are biologically relevant. It is worth noting, however, that sensitivity can be a double-edged sword – many of the low abundance metabolic components are derived from symbiotic or xenobiotic organisms (such as gut microflora) not directly related to mammalian metabolism. It is unclear whether gathering such enlarged metabolic datasets using highly sensitive analytical approaches is useful – indeed, it may simply make the task of extracting a meaningful picture from the resulting dataset more difficult (see Sect. 3).

The second factor is the invisibility of particular compounds, or more likely classes of compounds, to a particular analytical technique. An obvious example would be the inability of non-volatile components to contribute to a gas chromatograph. Less obvious might be the inability of a technique to separate or distinguish components with closely related structures, such that a single ''entry'' in the profile is in fact a composite measure of two or more compounds.

2. *Bias*. The ''ideal'' profile is not merely a list of the components present in the sample but also an indicator of the relative amounts of each component. Thus, if certain components are more readily detected than others (on a molar basis) the analytical technique will display a bias, suggesting some components are present at relatively higher levels than they actually are.
3. *Cost*. The resource implications of any data-gathering exercise must be properly considered as part of the scientific experimental design. This is particularly true of any nonselective, high data density ''omics'' experiment, where the amount of understanding about the system which is ultimately gained will likely depend on how many different (that is, uncorrelated) components of the system are analyzed, rather than whether any particular class of components (be it metabolites, proteins or genes) has been exhaustively investigated. Consequently, the resource implications of selecting any given analytical methodology rightly forms a part of the experimental design: does the additional information gained by adding a particular technique to the portfolio of analyses to be performed on a given sample add sufficient uncorrelated variables to justify the resources employed, or could the same resources generate more uncorrelated information through application of a different technique?

No technique currently available is complete, unbiased, and inexpensive, but each has certain advantages for particular applications. Application of multiple techniques to the same sample may improve completeness and reduce bias, but only at increased resource implication.

2.2 Nuclear Magnetic Resonance (NMR) Spectroscopy

NMR (nuclear magnetic resonance) spectroscopy has been widely used to generate metabonomic profiles, particularly of serum and urine samples. The primary advantages of NMR spectroscopy are the intrinsic reproducibility of the generated spectrum and the complete lack of bias. Across the information-dense region of the spectrum the coefficient of variation between replicate measures made on different days is below 1%. Reproducibility of this nature allows even small differences between profiles to be interpreted as significant, increasing the power of the experiment, particularly when relatively small numbers of profiles are being compared.

The NMR spectrum depends on the context-dependent resonance of hydrogen nuclei within the various molecules that compose the biological sample. As a result, any molecular structure containing at least one hydrogen nucleus is in principle represented within the spectrum. Since all biological molecules fall into this category, essentially every metabolite can contribute to an NMR-derived metabonomic profile. Furthermore, the intensity of the signal due to each hydrogen nucleus is of the same strength irrespective of its molecular context. Consequently, there is absolutely no bias in the estimated relative amounts of each of the metabolites detected.

Despite this lack of bias, NMR spectroscopy cannot be considered to generate a complete metabonomic profile because of the inherent insensitivity of the approach. Although the high reproducibility

allows even very small peaks to be distinguished from baseline noise, these peaks still represent relatively abundant molecular components of the sample. Although the absolute sensitivity cutoff varies depending on the particular implementation of the technique (for example, the use of cryoprobes significantly improves the sensitivity with nanogram quantities of compounds detected), nevertheless, very low abundance molecules are difficult to detect. Since many biological molecules of importance (such as vitamins and signaling molecules like prostaglandins or cyclicAMP) rarely achieve concentrations above the nM range, they are effectively absent from NMR-derived metabonomic datasets.

Although NMR spectroscopy is the tool of choice for most chemical structure determination problems, it also struggles to distinguish certain classes of closely related molecular structures. For example, it is difficult to study complex mixtures of fatty acids of different chain lengths by NMR spectroscopy, because the signals from the different molecular structures are overlaid in the resulting spectrum. Although ever more complex NMR-based approaches have been devised to aid separation and unique identification of given molecular structures (such as 2D-TOCSY or various heteronuclear NMR approaches), these approaches are resource intensive and may still be less informative than mass spectrometry for certain molecular classes.

2.3 Chromatography and Mass Spectroscopy (LC-MS and GC-MS)

Chromatography followed by mass spectrometry is the other major analytical tool that has been used to generate metabonomic profiles. Both liquid chromatography (LC) and gas chromatography (GC) have been used. GC may offer superior resolving power, at least for certain classes of molecules, but it is limited by the lack of volatility of many metabolites. Although this can be overcome to some extent by covalent modification of the sample prior to chromatography, a range of important metabolites still fail to enter the gas phase and hence do not contribute to the resulting metabonomic profile. As a result, the effective size limit for GC-MS is about 700 Da, whereas much larger molecules can contribute to the NMR-, and to some extent, to the LC-MS-derived profiles.

The major advantage of GC-MS and LC-MS is the sensitivity of the technique, which can detect component compounds down to the likely limit of biological relevance (and, indeed, may be too sensitive in some cases, populating the metabolic dataset with large numbers of minor contaminants of the sample, which are not the products of mammalian metabolism). As a result, components such as vitamins and signaling intermediates, which were invisible to the NMR spectrometer, now contribute to the GC-MS-derived metabonomic profile.

The combination of chromatography and mass spectroscopy (MS) can also allow unambiguous assignment of structure to the components of the biological sample in a way that is difficult, though not impossible, with NMR spectroscopy. Comparison of fragmentation patterns with databases, allows deconvolution of peaks with overlapping retention times, and as many as 1000 different molecular components to be unambiguously identified from a single complex biological fluid. This is particularly true when comparing different members of the same homologous series (such as fatty acids of

different chain lengths). However, LC-MS and GC-MS usually poorly resolve structural isomers that are readily distinguished by NMR spectroscopy. It is also important to note that, unlike NMR spectroscopy, mass spectrometry cannot be used to obtain the structure of unknown components contributing the profile – if the fragmentation pattern is not among the database of ''known'' metabolites, no assignment is possible.

Furthermore, MS-based detection is inherently biased: some molecules do not ionize, or only ionize poorly, under any given set of conditions and as a result are either completely invisible or detected only weakly. Consequently, an MS-derived metabonomic profile may be highly biased, and little information can be gained from the relative signals due to different components in the biological sample. However, it is still possible to compare the levels of the same component across different samples in a reliable and reproducible way. Again, variations in the implementation of the technique (such as using both positive and negative ionization modes and varying the cone voltage) can alleviate, though not eliminate, this problem at the cost of increased resource implication.

2.4 Nanosensors

More recently, it has become clear that various designs of the nanosensor can also be applied to generating metabonomic profiles. Nanosensors coated with various hydrophobic coatings adsorb a wide range of metabolites differentially, allowing a profile to be generated that is related in a complex fashion to the molecular composition of the fluid under study. Although to date, no metabonomic profile that has been generated using nanosensor technology has been reported in the scientific literature, it seems likely that such datasets will appear imminently.

Nanosensor-derived metabonomic profiles will presumably have the advantage of low cost (being rapid and high throughput, and not requiring capital intensive reading equipment). However, the complex nature of the relationship between the resulting data vector and the molecular composition of the sample will likely preclude any straightforward listing of the component molecules or estimation of the relative amounts. Such a profile will be neither substantially complete nor unbiased.

Yet, at least for clinical diagnostic applications, such profiles are not without utility. Although it may be difficult (or indeed impossible) to understand precisely which molecular components contribute to the systematic difference in profiles between two groups of interest (such as diseased individuals versus healthy individuals), nevertheless, the very presence of a systematic difference may be diagnostically useful.

2.5 Other Approaches

Many other analytical chemistry techniques can be applied to complex biological fluids to generate a metabonomic profile, although (like nanosensors) such profiles cannot usually be translated into a list of molecular components with associated relative concentrations. For example, infrared spectroscopy provides a low-cost approach to generating a metabonomic profile, which may be useful in some circumstances. It may be possible, depending on the nature of the biological

sample and the particular molecular components of interest, to generate a limited list of molecular components from an infrared spectrum.

Ultimately, however, the utility of a metabonomic profile obtained with any given technique depends on the application. Many studies (particularly aimed at diagnostic applications) may not require the immense structural detail that can be generated using the resource-intensive NMR and MS techniques. Equally, attempts to identify biomarkers associated with a particular phenotype will require a metabonomic profile that more nearly corresponds to the theoretical "ideal" profile. There remains, therefore, a considerable amount of trial and error in the selection of the analytical toolkit best suited to answering a particular question.

3
Methods for Interpreting Metabolic Profiles

3.1
The Problems of Interrogating Very Large Datasets

Much of the power of the metabonomic approach stems from the generation of very large datasets, which are essentially unselected in terms of the contributing components (that is, there was no preexisting hypothesis governing the selection of variables to be measured). As a consequence, special techniques are required to handle the resulting datasets, since extracting meaningful conclusions from datasets with millions of datapoints is a daunting exercise.

The basic aim in interpreting a metabonomic dataset is no different from any conventional multivariate analysis. The value of a dependent (or *Y*-) variable is estimated from a collection of measured *X*-variables (Fig. 3). For example, one might wish to estimate blood pressure from a range of physiological (or metabonomic) measures. While the *Y*-variable to be estimated (or "modeled") may be continuous (like blood pressure), it may equally be a discrete classification variable (which divides each observation into two or more groups, such as the presence and absence of a particular disease).

The problems associated with analyzing very large datasets are basically twofold. Firstly, a metabonomic profile might typically be composed of thousands of datapoints for each individual, yet such a profile may only have been generated from a relatively small number of individuals (tens or at most hundreds per group). Such datasets are typically described as "short and fat," having many more variables than observations (illustrated in Fig. 3). Analyzing such short and fat datasets using conventional multivariate statistics is dangerous, because it becomes increasingly likely that you can construct a model that correctly describes the phenotypic classification of the individuals by chance alone as the number of variables exceeds the number of observations.

Secondly, many of the variables that compose the metabolic profile may be highly correlated with each other. This is a particular problem with spectroscopic data, where neighboring variables are integrals of a continuous spectrum, forcing a relationship between nearby spectral regions. Conventional statistical approaches to multivariate analysis assume that all the predictor variables are independent, and the widespread colinearity of metabonomic profile variables renders the conventional multivariate models error prone.

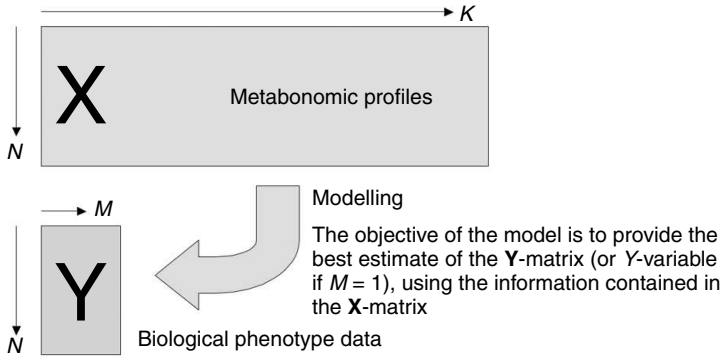

Fig. 3 The principle of regression modeling. The principle of regression modeling is to predict a range of features about a complex system (such as a biological organism) from a collection of unrelated measurements. In metabonomics, this consists of predicting phenotype or behavior (a **Y**-matrix of *M* features of *N* individuals) from a metabonomic dataset consisting of *K* measured metabolic variables from the same *N* individuals. Unlike conventional regression modeling, metabonomics datasets are typically ''short and fat'' with many more measurements per observation than individuals ($K \gg N$). The **Y**-matrix to be predicted might be a single continuous variable ($M = 1$), or even a categorical description (diseased or healthy, for example), whereupon the modeling is usually termed *a discriminant analysis*. Figure reproduced with permission from www.graingerlab.org.

3.2 Conventional Statistical Approaches (LDA)

As noted above, a conventional multivariate model (in which a dependent variable (Y) is predicted from a matrix of independent variables) is based on the assumption that the number of X-variables is less than the number of observations (n), and that all the X-variables are uncorrelated. In most experiments, a series of raw metabonomic profiles violates both assumptions and as a general rule conventional multivariate statistics should not be applied to metabonomic datasets.

However, various preprocessing steps can convert the raw metabonomic dataset into a form amenable to conventional statistical analysis. For example, there exists a range of prefilter algorithms (see Sect. 3.6 below) that allow the number of X-variables to be substantially reduced, for example, by retaining only those X-variables that are most significantly correlated with the dependent variable Y. Such variable-selection algorithms may also incorporate rules to eliminate intercorrelated X-variables. After variable selection, the resulting dataset can be analyzed by conventional multivariate statistics, such as linear discriminant analysis (LDA).

Although such variable-selection approaches circumvent the limitations of conventional multivariate statistics, they can limit the power of the analysis to identify associations between the **X**-matrix and the dependent Y-variable, since much of the information in the **X**-matrix has been discarded. In general, therefore, the other approaches below (which have been developed specifically for the analysis of very

large, or megavariate, datasets) tend to be more powerful.

3.3 Projection Methods (PCA and PLS)

Instead of selecting a subset of variables from the **X**-matrix, it is possible instead to combine the *X*-variables in linear combinations to generate a smaller number of composite variables. This approach (termed *projection*) deals effectively with both of the limitations to megavariate analysis: variable number is reduced, and intercorrelation is minimized.

The principle of projection is illustrated in Fig. 4. Here, a complex 3-dimensional object is represented by a simpler 2-dimensional shadow. In the left panel, the axis of projection is chosen such that the 2-D shadow poorly retains the information of the original object, whereas in the right panel the optimum projection is chosen, which retains most of the information encoded in the original 3-D object. The mathematical algorithms that underlie projection methods such as principal component analysis (PCA) or projection to latent structures using partial least squares (PLS) work by selecting the best projections. A major difference between PCA and PLS is that PLS is a supervised method, which means that the dependent *Y*-variable is used in the process of locating the best projection of the data. Application of these algorithms to high-dimensional datasets (such as metabonomic profiles) can yield just a handful of composite variables (principal components), which are simple linear combinations of the original matrix of *X*-variables. Unlike simpler variable-selection techniques, projection retains as much as possible of the information in the original **X**-matrix, while reducing the dimensionality of the dataset to manageable proportions.

One potential problem with projection methods is overfitting the model. With a sufficiently large number of *X*-variables, it will always be possible to generate combinations of the *X*-variables that predict the dependent variable very well. As a result, it is essential to include a robust external model validation step in the analysis protocol. One example of a useful validation step is scrambling the dependent variable and demonstrating that the **X**-matrix predicts the real dependent variable better than the scrambled variable. An alternative approach is to use the generated model to make predictions about an external dataset not used during model generation. Exhaustive validation is essential for models built using supervised techniques, such as PLS, where the dependent variable was

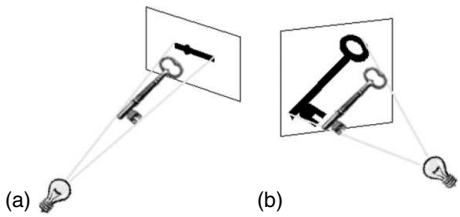

Fig. 4 The principle of projection. A complex high-dimensional object can be represented by a simpler, lower-dimensional model by projection. This is illustrated by the 2-D shadow of 3-D object such as key. However, depending on the particular projection selected, the 2-D model may be poorly representative of the original 3-D object (panel A). The aim of projection modeling tools such as PCA or PLS is to select the optimum lower-dimensional representation of the original complex object (right panel). Figure reproduced with permission from www.graingerlab.org.

used during the construction of the principal components.

3.4 Genetic Computing

Another approach to building models that optimally describe a dependent *Y*-variable from a very large **X**-matrix is to generate a large pool of random models (that are linear or nonlinear combinations of the *X*-variables), a few of which will be acceptable but most of which will be poor, and then apply an evolutionary algorithm to recombine the models and select for improved description of the dependent variable. The evolution is continued through a number of generations, and models can emerge that explain a good proportion of the variation in the *Y*-variable.

This approach can offer a number of advantages over projection-based methods. In particular, the ability to easily include rules that combine *X*-variables in nonlinear ways can be useful when modeling biological systems that have inherent nonlinearities. Another advantage of the evolved models is that they are generally easier to interpret than the optimized projection models. Combinations of simple rules can be more intuitively obvious than lists of principal components

One disadvantage of genetic computing approaches, however, can be ''premature convergence'' whereby the pool of models undergoing evolution rapidly converges on a local maximum of fitness and poorly explores the entire model space. Improvements are continually being made to the basic genetic computing algorithms, and recent advances such as multiobjective fitness functions can alleviate the premature convergence problem.

3.5 Other Approaches

The explosion of high data density analytical techniques in genomics and proteomics, as well as metabonomics, has stimulated the development and refinement of a wide range of other bioinformatics tools to assist in the interpretation of very large datasets. Hierarchical cluster analysis (HCA) is particularly popular for the analysis of gene expression datasets, but it is considerably less powerful than both projection methods and genetic computing algorithms, while offering few advantages. As a result, HCA has not been extensively used to interpret metabonomic datasets.

Another approach, which has been used in metabonomics, is neural network analysis. The neural net is set up with the *X*-variables as inputs and the dependent *Y*-variable as output, with a network of nodes in between. The mathematical function applied at each node is then iteratively varied during a learning phase to optimize the successful prediction of the *Y*-variable. Neural nets can be useful for performing discriminant analysis (that is, classifying observations into two or three groups on the basis of their **X**-matrix values) and hence used for clinical diagnostic purposes, but the models they generate are inherently difficult to interpret, because a large number of structurally different models can yield almost identical predictive power.

3.6 Data Preprocessing and Data Filters

Model building with very large datasets may be best performed in two or even more steps. Rather than directly applying one or more of the model building tools

described above to the raw **X**-matrix, it may be more powerful to perform a preprocessing step first. In fact, as with the model building tools themselves, the object of most of the preprocessing steps is to reduce dimensionality. However, empirical observation suggests that more powerful models can be generated if the dimensionality is reduced in stepwise fashion, perhaps using more than one tool, rather than in a single leap.

Consequently, the most straightforward preprocessing step would be to apply one of the model building tools twice in succession. For example, with projection methods, it is possible (and sometimes useful) to perform an initial principal component analysis reducing the dimensionality of the raw **X**-matrix from, say 8096 variables to tens or hundreds of principal components, and then treat the resulting matrix of principal components as the **X**-matrix for a second round of PCA to reduce the dimensionality down to two or three components, which can be more readily interpreted. The extent to which such hierarchical PCA improves the model compared with application of a single round of PCA depends very much on the particular data structure.

When dealing with metabonomic profiles derived from continuous spectra (such as an NMR spectrum), the neighboring variables (derived from integration of contiguous regions of the spectrum) can be very highly correlated. The shorter the interval along the abscissa that composes each variable, the higher is the degree of local intercorrelation. This can be reduced by integrating over wider intervals (or by averaging neighboring integrals, a process termed *binning*). This effectively reduces the dimensionality of the spectral data, while retaining much of the important information encoded in the spectrum.

Binning relies on the fact that the most highly intercorrelated variables are related to each other by their position along the abscissa in linear fashion. This may not be true for all types of data; in some cases, the most intercorrelated variables may fall cyclically (for example, in the untransformed free-induction decay signal from an NMR spectrometer). For analyzing such datasets, wavelet transformation, rather than binning, will provide the most efficient dimensionality reduction prior to model construction.

Finally, noise filters can be applied to the dataset prior to model building, and for NMR-derived metabonomic datasets this has been shown to significantly improve the performance of projection-based modeling tools. Noise filters (such as orthogonal signal correction; OSC) aim to remove variation in the **X**-matrix, which is uncorrelated with the dependent *Y*-variable, simplifying the dataset for subsequent modeling. It is important to remember that noise filters like OSC are therefore supervised methods, and exhaustive validation of models built on the filtered dataset will be required irrespective of the nature of the modeling tool subsequently used.

4
Applications of Metabonomics

4.1
Probing Normal Human Metabolism

The most obvious application for metabonomics is to aid understanding of normal human metabolism. It is possible to build up a detailed picture of metabolic pathways by taking a time series of metabolic profiles and constructing quantitative models describing the metabolic flux through

various pathways. Although the properties of key metabolic pathways (such as glycolysis or tricarboxylic acid cycle) have been extensively investigated for years, metabonomics can still reveal important aspects of metabolism, which had previously gone unnoticed. In particular, the interaction between endogenous metabolic pathways and the products of symbiotic bacterial metabolism have been extensively investigated using metabonomics.

4.2 Probing the Pathophysiology of Human Disease

Metabonomics is particularly powerful for analyzing the metabolic changes associated with the development of a particular disease state. By comparing metabonomic profiles taken from diseased individuals with profiles from healthy control individuals, it is possible to identify the systematic differences associated with the presence of the disease. What remains challenging, however, is determining which (if any) of these metabolic changes are causes of the disease pathology, as opposed to direct or even indirect consequences of the disease progression.

For example, metabonomics has been used to investigate the metabolic changes associated with the development of osteoporosis. Serum samples from women with low bone mineral density and from healthy control women were subjected to ^{1}H-NMR analysis, and the resultant profiles compared using the projection method PLS-DA following an OSC prefilter. One of the most important metabolites responsible for the separation of the diseased and healthy individuals was the amino acid proline. Women with pathological low bone mineral density had lower levels of proline in their serum; an observation that was later confirmed used conventional biochemical assays. While this does not prove that low serum proline is responsible for the lower bone density, it is a plausible hypothesis for further investigation: proline is a key constituent of the collagen component of bone matrix, and inadequate proline supplies for collagen biosynthesis could represent an entirely novel pathophysiological mechanism in the development of osteoporosis.

4.3 Investigating and Validating Animal Models of Disease

Animal models of human diseases are important tools in scientific and pharmaceutical research and development. The development of genetic manipulation techniques has allowed good models of many monogenic disorders (such as muscular dystrophy) to be developed, confident in the knowledge that the underlying cause of the disease is similar in the animal as in man. In contrast, for complex polygenic disorders such as atherosclerosis or Alzheimer's disease, it is unclear to what extent any given animal model mimics the molecular mechanisms underlying disease susceptibility in man, even if the phenotype of the animals faithfully mirrors the human disease.

Metabonomics offers an opportunity to address this question. Metabolic profiles of animal models can be compared directly with the profiles from human sufferers, allowing a comparison of the physiological perturbations accompanying disease development in the two species. Perhaps more powerfully, it should be possible to track the metabolic trajectory of both animals and humans as the disease progresses, with similar trajectories increasing the confidence in the likely validity

of the model. Studies of this nature are currently underway for a range of animal models of disease, but to date none have been published.

4.4 Clinical Diagnosis of Disease

In many senses, using metabonomics to perform clinical diagnoses is more straightforward than its application to biomarker identification and pathophysiological analysis. Providing a clinically useful diagnosis of a disease on the basis of a serum sample only requires the identification of a robust metabolic signature that always accompanies the disease and is rarely, if ever, present in healthy control individuals. It is not necessary to be able to identify any of the molecular components contributing to the disease-associated metabolic signature.

For example, projection analysis using PLS-DA of ^{1}H-NMR-derived metabonomic profiles of serum samples from individuals with coronary artery disease and healthy control individuals demonstrated clear separation of the two groups. After application of the OSC prefilter, it was possible to predict the disease status of individuals with at least 90% sensitivity and specificity. This metabonomics diagnostic test outperforms all existing noninvasive tests for coronary heart disease by a considerable margin. Although such a test is potentially useful in the clinic (since, at present, the gold-standard diagnostic test for heart disease is an invasive angiography procedure that is expensive and carries a small risk to the patient), it does not readily identify the particular molecular species responsible for separating the two groups. Much of the discriminatory power of the test falls in the region of the NMR spectrum due to lipid components (unsurprisingly, given our knowledge of the mechanisms underlying heart disease) but NMR poorly resolves these closely related lipid structures and considerable further work will be required before the precise molecular basis for the success of the test is known.

4.5 Selection of Subjects for Clinical Trials

At present, a substantial impediment to the testing of new therapeutics for certain diseases is the ability to identify potential sufferers ahead of time. For example, to test a drug proposed to reduce the incidence of myocardial infarction requires the recruitment of subjects at high risk of suffering a myocardial infarction during the trial. Unfortunately, current methods of identifying such subjects are poor, and trials of this nature can require the study of thousands of individuals for three years or more to accumulate sufficient myocardial infarction events for the impact of the drug to be detectable. Although metabonomics-based diagnostics have yet to be used in such applications, it is likely that their widespread adoption will rapidly follow the first successful demonstration of such use.

4.6 Monitoring Efficacy of Therapeutic Interventions

One of the most exciting applications of megavariate diagnostics, whether based on metabonomic, genomic, or proteomic profiles, is the prospect of personalized therapeutic interventions. At present, many drugs are used on broad swathes of the population (for example, statins to lower circulating LDL cholesterol) without any clear indication as to whether they are equally effective in all individuals. Pilot

studies already indicate that it is possible to predict the response of an individual to statin therapy from their metabonomic profile measured prior to beginning therapy. Such ''pharmacometabonomics'' could be extended to optimize the dose and delivery route of a wide range of drugs for each individual, with likely improvements in the efficacy of treatment.

4.7 Toxicology

Perhaps the most mature application of metabonomics is the application of metabolic profiling to toxicology. By studying the metabolic response to a range of model toxins (with organ-specific toxicity), it has been possible to identify metabolic signatures associated with damage to a particular organ. Extensive studies following the metabolic trajectory of animals treated with these model toxins have been published, although commercial considerations mean that few studies of clinically relevant pharmaceutical compositions have reached the public domain.

While metabonomics may help improve the predictivity of animal toxicology studies (which are notoriously difficult to interpret using conventional physiological and histological end points), perhaps the most exciting possibility is the use of metabonomics to perform early stage toxicology directly in man. Because of the sensitivity of metabonomics to detect minute perturbations in the metabolic signature, it may be possible to get an indication of the mode of toxicity of novel chemical entities given in man at doses well below those at which any irreversible damage might occur. The ability to perform meaningful toxicology in man should improve the safety of our medications, and at the same time reduce the number of promising pharmaceutical compounds dropped at a relatively late stage in development because of adverse, and possibly species-specific, side effects observed in the animal models currently used for toxicology.

4.8 Predicting Future Disease Risk

If a metabonomic profile can be used to diagnose the presence of an existing disease (such as coronary heart disease or osteoporosis), there is no reason in principle why it cannot be used to predict future disease susceptibility in the same way that genomic profiles are currently being used. To provide a useful indicator of future disease risk, there must be a component of the dynamic metabolic profile that is temporarily stable on a timescale of years and that is variable between individuals. We have already shown that such a stable interperson variance component exists in NMR-derived metabonomic profiles, and it will be interesting to see to what extent this stable element of the metabolic profile predicts the risk of a range of important diseases.

5 Future Prospects and Challenges

The discipline of metabonomics is expanding rapidly. Although selection from among the many combinations of analytical chemistry and mathematical modeling approaches for any given applications remains empirical, nevertheless, the number of metabonomics studies is growing quickly. Successful examples of the use of metabonomics to answer a broad array of scientific and practical questions are now plentiful in the literature (see

Sect. 4), and application to an ever-broader array of problems seems inevitable. Indeed, it is hard to think of a problem that would not be better addressed by a combination of high data density ''omics'' approaches than by hypothesis-driven reductionist experimentation. It seems that only a deep-seated unease among much of the scientific community for such exploratory, holistic approaches relegates the typical metabonomics experiment to ''second-class status'' and hampers an even more rapid expansion.

One of the challenges facing metabonomics over the coming years, therefore, is to better understand which of the many experimental approaches is optimum for a given use. Doing so will likely require the careful analysis of a single sample set by multiple different analytical chemistry techniques, and then each resulting dataset be interpreted using a range of mathematical modeling tools. In this way, the comparative power of the different approaches will begin to emerge.

Another important challenge is the integration of metabonomics datasets with the large profiles generated by other high data density techniques such as genomics or proteomics. In a sense, the division of ''omics'' science along the lines of the analytical techniques needed to make the measurements is entirely arbitrary. Ultimately, it should prove powerful to combine the profiles obtained from multiple different measurement approaches (whether gene expression, protein levels, or metabolite profiles) into a single ''multi-omics descriptor.'' While there remains considerable debate as to exactly how this amalgamation should be performed, it is widely acknowledged that such a system-wide profile is likely to prove more powerful than a metabonomic or genomic profile alone for many applications. Only such a system-wide profile can allow a complete understanding of such a complex system as a biological organism.

Keywords

Cytochrome P-450
Refers to a family of heme monooxygenases, present in certain pseudomonads and most mammalian cell types, that catalyze the oxidation of a wide variety of structurally diverse compounds.

Electrophilic Catalysis
Refers to the electrostatic stabilization of a negative charge that develops in the transition states of certain reactions.

Metalloprotease
An enzyme, typically containing Zn, that catalyzes the hydrolysis of peptide bonds.

Oxidase
An enzyme that catalyzes an oxidation using O_2 as the electron acceptor; O atoms from dioxygen are not incorporated into the product of the oxidation.

Oxygenase
An enzyme that catalyzes the reaction of O_2 with an organic substrate in which oxygen atoms (one in the case of monooxygenases; two in the case of dioxygenases) from dioxygen are incorporated into the product.

Peroxidase
An enzyme that catalyzes the oxidation of an organic/inorganic substrate by hydrogen peroxide.

Superoxide Dismutase
A metalloenzyme that catalyzes the disproportionation of superoxide, forming hydrogen peroxide and O_2.

Urease
A nickel enzyme that hydrolyzes urea, forming ammonia and carbamate.

Metalloenzymes, which comprise approximately one-third of the known enzymes, require stoichiometric quantities of metal ions as cofactors, typically transition metal ions, for their catalytic activities. The roles of metal ions in enzyme active sites (aside from structure maintenance) include electron transfer, oxygen atom transfer, formation of coordinated hydroxide, electrophilic catalysis, as well as substrate binding. Metalloenzymes catalyze numerous reactions of physiological importance, including mitochondrial O_2 reduction, peptide bond cleavage, hydrocarbon hydroxylation, destruction of O_2^- and H_2O_2, and hydration of CO_2.

1 Occurrence

1.1 Discovery

The study of metalloenzymes has its roots in investigations that took place more than a century ago. In 1897, Gabriel Bertrand, working on laccase (a polyphenol oxidase), suggested for the first time that a metal ion was essential for the catalytic activity of an enzyme. At this time, the nature of enzymes was a matter of vociferous debate – Are enzymes protein-based catalysts, or is the catalysis traceable to low-level contaminants? In 1926, James Sumner presented a pivotal result: crystallization of jack bean urease, demonstration that urease is a protein, and that the dissolved crystals catalyze the hydrolysis of urea. Sumner, who failed to detect any metal ions in his urease preparations, expressed the view that metal ions are unlikely to play important roles in the enzymatic catalysis of biological reactions. It is ironic that 49 years after Sumner's pioneering crystallization of an enzyme, urease was subsequently found to contain nickel ions, which are essential for enzyme activity!

Prior to the development of modern methods for trace element analysis and spectroscopic instrumentation, many metalloenzymes (e.g. blue copper oxidases) were initially isolated simply because they were a colored component of a cell or tissue homogenate. During the last 40 years, numerous nonchromophoric metalloenzymes have been isolated as well. Our current understanding of metalloenzymes is largely based on enzymes containing iron, copper, or zinc. Numerous examples of enzymes containing other metals (Mg, Ca, Mn, Co, Ni, V, Mo, W) are also known; however, the structural and mechanistic information currently available for these is less detailed.

1.2 Biological Importance

Metalloenzymes play key roles in many processes central to human physiology, including the biosynthesis of DNA and certain amino acids, steroid metabolism, destruction of superoxide and hydrogen peroxide, biosynthesis of leukotrienes and prostaglandins, carbon dioxide hydration, neurotransmitter metabolism, digestion, collagen biosynthesis, and, of course, respiration. The latter could be viewed as a process of global bioenergetic importance, one that complements photosynthesis – the dioxygen that is evolved (via the Mn_4 oxygen-evolving complex of Photosystem II) by photosynthetic organisms is consumed by aerobic microbes and animals (Fe, Cu cytochrome oxidases catalyze the reduction of O_2 to H_2O).

Within the last 25 years, it has become widely appreciated that metal ions play important catalytic roles that frequently cannot be matched by protein side chains or organic prosthetic groups. The most significant observation of this type concerns the microbial fixation of molecular nitrogen, a very inert molecule:

$$N_2 + 6H^+ + 6e^- \longrightarrow 2NH_3 \qquad (1)$$

This reaction is catalyzed by nitrogenase, whose active site consists of a dissociable Mo- and Fe-containing cofactor. The catalysis of such multielectron redox reactions is frequently carried out by metalloenzymes containing multimetal centers (i.e. metal clusters).

1.3 Metal Ion Bioavailability

Only a small number of the metallic elements appear to be utilized in biology. Of these, Na^+, K^+, Ca^{2+}, and Mg^{2+} are considered macrominerals, or bulk elements; high concentrations of these ions are needed for osmotic homeostasis, neuromuscular transmission, and biomineralization (e.g. bone formation). As indicated in Table 1, other essential metals are present in trace quantities in humans and most other organisms. Even the most prominent biologically active transition metals (iron, zinc, and copper) are trace elements.

The selection of metal ions for incorporation into metalloenzymes is strongly influenced by bioavailability – a given element must be abundant in the environment and must be present in an extractable form. A striking exception to this generalization involves the nearly universal requirement for iron. Organisms have evolved selective uptake mechanisms for this element, the most abundant transition metal in the earth's crust, which forms insoluble ferric hydroxides in the presence of O_2. The incorporation of metal ions into metalloenzymes is also influenced by other, chemically oriented, parameters such as ionic radius, charge, preferred coordination geometry, ligand substitution and redox kinetics, aqueous solution chemistry, and thermodynamic stability.

Tab. 1 Essential metal composition of a 70-kg human adult[a].

Element	*Composition (wt%)*
Ca	1.4
Na	0.63
K	0.26
Mg	4×10^{-2}
Fe	5×10^{-3}
Zn	3×10^{-3}
Cu	1×10^{-4}
Mn	2×10^{-5}
Mo	2×10^{-5}
Ni	4×10^{-6}
Cr	4×10^{-6}
V	3×10^{-6}
Co	2×10^{-6}

[a] Note: O,C,H,N,P,&S constitute 97.6 wt%.

1.4 Active Site Assembly

Incorporation of a metal ion, a posttranslational biosynthetic event, requires that the folding of the polypeptide chain permit several side chains to congregate to form an appropriate metal-binding site. The primary metal-binding amino acid side chains are imidazole (His), carboxylate (Asp and Glu), thiol (Cys), thioether (Met), and hydroxyl (Ser, Thr, and Tyr). Less frequently, indole (Trp), guanidinium (Arg), and amide (Asn and Gln) groups are used. Backbone carbonyl groups can also participate in metal binding. The side chain functional groups must usually be deprotonated in order for a donor atom (O, N, or S) to form a metal–ligand bond.

Some metal ions coordinate to their binding sites in apo-metalloenzymes as simple aqua ions. For example, Zn^{2+} binds to apo-carbonic anhydrase in a multidentate ligand reaction: the metal ion sheds coordinated water molecules as it binds to the active site of the apoenzyme, which could be viewed as an elaborate chelating agent. However, redox-active metal ions (e.g. Cu, Fe, Mn, Mo) pose special problems by virtue of their reactivities with O_2^- and H_2O_2. For example, it has become clear during the last decade that pools of soluble copper ions are not used in the physiological activation of eukaryotic

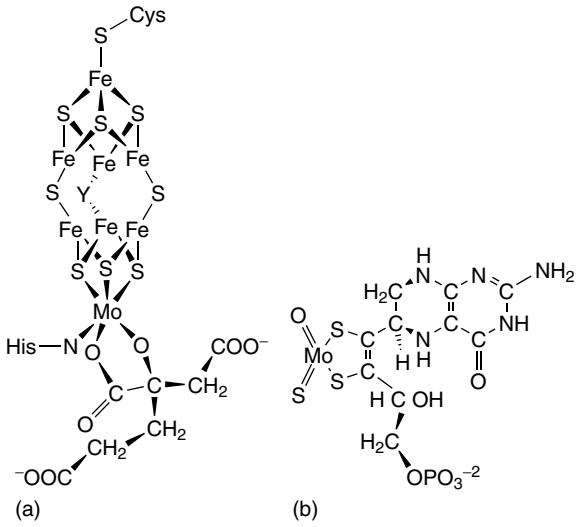

Fig. 1 Molybdenum cofactors: (a) Structure of the FeMo cofactor of *Azotobacter vinelandii* nitrogenase. The cofactor is bound to the enzyme via the indicated cysteine and histidine residues. Homocitrate is bound to the molybdenum center. (b) Proposed structure of the oxidized molybdopterin cofactor (Mo-co) of mammalian molybdenum enzymes.

copper enzymes, such as Cu,Zn superoxide dismutase and cytochrome *c* oxidase. Copper ions are known Fenton reagents ($OH^{\bullet}$ generators), and their sequestration is a straightforward way of circumventing unwanted redox reactions. Intracellular copper delivery is mediated by ''chaperone'' proteins that form complexes with their apoenzyme targets prior to metal-ion exchange. Emerging research results indicate that chaperones likely exist for other redox-active metals as well.

The biosyntheses of some metalloenzymes of physiological importance requires the prior synthesis of a specialized organometallic complex. Such species include vitamin B_{12} (a cobalt corrin), hemes, and molybdenum cofactors (Fig. 1). Molybdoenzymes contain unusual metal-containing cofactors that have been shown to be traceable to the participation of accessory biosynthetic genes. The FeMo cofactor (FeMoCo) of nitrogenase also illustrates a more complex phenomenon – the use of metal clusters as cofactors in enzymes. Such aggregates typically utilize sulfide or oxide (hydroxide) ions as bridges between metal centers. Sometimes (e.g. the iron–sulfur cluster of aconitase) the cluster assembles in a stepwise fashion after apoenzyme biosynthesis. In other cases (e.g. the nitrogenase FeMo cofactor), accessory proteins, ''molecular scaffolds'', are needed for complete cluster assembly; the cluster is subsequently transferred to the apoenzyme to complete the biosynthesis of the mature metalloenzyme.

2 Active Site Characterization

2.1 Metal Content

Traditional methods of trace element analysis have relied on the use of techniques best suited for quantitative, rather than qualitative, analysis such as complexometric titrations, colorimetric procedures, or atomic absorption spectrometry. Determinations of the metal contents of putative metalloenzymes have frequently

been in error, owing to impure enzyme preparations, cofactor loss during purification, or inadequate analytical techniques. The most suitable methods for qualitative metal analysis include X-ray fluorescence spectrometry, neutron activation analysis, and atomic emission plasma spectrometry. Many metalloenzymes contain more than one kind of metal ion; hence, both qualitative and quantitative metal analyses should be done whenever possible.

A key indicator of metal-activated enzyme turnover is the ability to abolish the activity by adding a metal chelator (usually EDTA) or a small molecule (e.g. CO, CN^-, N_3^-, carboxylic acids) that is known to bind to metal ions in proteins and coordination compounds. Further proof of the nature of the native metal ion often requires tedious trial-and-error studies to determine which metal gives the greatest enzyme activity.

2.2 Physical Methods

Going beyond the determination of metal content, to demonstrate that a particular metal ion is present at the active site of a metalloenzyme, requires spectroscopic and/or X-ray crystallographic experimentation. Detailed structures, derived from X-ray crystallographic or nuclear magnetic resonance analyses, are available for less than 5% of the known metalloenzymes. Other physical methods have therefore been used in obtaining information about physicochemical properties these enzymes, such as hydrodynamic radius, substrate-binding constants, or types of ligands bound to the metal(s).

Extended X-ray absorption fine structure (EXAFS) spectroscopy can provide information about a primary metal coordination environment that is comparable with that obtained from X-ray crystallography – numbers and types of ligands, metal–ligand bond lengths, and bond angles. Other spectroscopic methods (e.g. infrared, Raman, electron spin resonance, fluorescence, electronic absorption), while much less informative, can nonetheless yield valuable information about the ability of an active-site metal ion to bind exogenous ligands (e.g. inhibitors) and about the likely oxidation state(s) in cases involving redox-active metals. In cases involving redox-active metal ions, determining the metal-ion oxidation states is an important prelude to formulation of enzyme turnover mechanisms. In the past, controversies arose because of proposed metalloenzyme mechanisms that invoked unusual oxidation states (e.g. Cu(III)) that subsequently were shown to be incorrect. Sometimes, metal–ligand bonds (especially involving Cys, O_2, S^{2-}, O^{2-} ligands) have such a high degree of charge transfer that assignments of metal-ion oxidation states are difficult.

Redox metalloenzymes usually undergo pronounced color changes during enzyme turnover, making optical spectroscopic studies particularly valuable. This first became evident with the early twentieth-century publications by Michaelis and Menten of observations on the turnover of horseradish peroxidase, a heme enzyme. Changes in the visible region of the spectrum during turnover (due to formation of transient intermediates) led them to formulate the Michaelis–Menten model of enzyme action.

Determinations of redox potentials of resting forms of redox enzymes yields valuable information that can be used to set constraints on proposed enzyme mechanisms. In some cases, notably the heme enzymes horseradish peroxidase and yeast

cytochrome *c* peroxidase, electrochemical methods have been used to generate unstable intermediates (ferryl hemes) for spectroscopic study and determination of their redox potentials.

2.3 Metal/Ligand Substitution

Metalloenzymes frequently contain metal cofactors that are spectroscopically useless. For example, zinc enzymes are diamagnetic and colorless – electron spin resonance or electronic absorption spectroscopy are therefore uninformative. However, information about the environment of the metal-binding site can be obtained by replacing the Zn^{2+} ion with a paramagnetic, chromophoric metal-ion probe. Co^{2+} readily replaces Zn^{2+} – they prefer similar coordination environments, have comparable ionic radii, and display similar reactivity patterns. The resultant cobalt-substituted enzyme can be characterized with regard to intermediates formed during enzymatic turnover. Furthermore, the use of metal derivatives can also indicate whether the metal binding site is rigid or flexible.

Obtaining the structure of a metalloenzyme is only the first step in developing an understanding of its physiological function. The production of recombinant derivatives affords opportunities to address additional issues, such as endogenous ligand exchange at the active-site metal(s) and participation of nearby amino acid residues in substrate binding/release, proton transfer, and/or electron transfer. Fast kinetic techniques (stopped-flow spectrophotometry, freeze-quench trapping of intermediates, flash photolysis, temperature-jump relaxation) are typically used to map out the individual steps that characterize the turnover of a metalloenzyme. In many cases, individual steps are too fast to accurately measure. One commonly used application of such techniques is the study of absorption spectra of transient enzyme intermediates generated by photolyzing carbon monoxide adducts of reduced heme enzymes in the presence of O_2. What tends to be overlooked in interpretations of structure and reactivity data is the importance of protein fluctuations (particularly in substrate binding and product release) – metalloenzymes are much more than metal ions in disguise.

3 Representative Metalloenzymes of Medical Importance

3.1 Functional Roles of Metal Cofactors

There are two principal types of metal-dependent enzyme. Metalloenzymes contain at least one tightly bound metal ion, at the active site, that is required for activity. Metal-activated enzymes, on the other hand, generally lose catalytic activity during purification because their affinity for the required metal is rather low. Mg^{2+}-, K^{+}-, and (most) Ca^{2+}-dependent enzymes are metal-activated and will not be discussed further. Na^{+}-dependency has yet to be unequivocally demonstrated for an enzyme.

Examples of metalloenzymes are known for each class of enzyme designated by the International Union of Biochemistry and are as follows: oxidoreductases, transferases, hydrolases, lyases, isomerases, and ligases. The following properties of metal ions make them well suited as catalysts for these types of reactions:

1. Metal ions bind at least three (usually four or more) ligands, thereby promoting the organization of protein structure.
2. With the notable exception of zinc, all of the other known transition metal cofactors can potentially exist in two or more oxidation states; metalloenzyme catalysis of oxidation-reduction (redox) reactions is thus quite common.
3. Metal-ion cofactors are electrophilic and can serve as effective Lewis acids for binding and activating substrates.

Two types of metal-ion reactivity are of fundamental importance in considering the wide range of activities displayed by metalloenzymes: changes in oxidation state and changes in bound ligands. Numerous examples of electron-transfer metalloproteins (blue copper proteins, iron–sulfur proteins, cytochromes) are known; the metal coordination spheres of these electron carriers do not change during electron transfer. Metal ions possessing static coordination spheres could alternatively play purely structural roles, as do Ca^{2+} in calmodulin, horseradish peroxidase, or stromelysin.

Certain metals (e.g. Zn^{2+} in carboxypeptidase A) cannot undergo redox reactions within the constraints imposed by nature; instead, acid–base catalysis is the *raison d'être* for the metal in the enzyme. Lastly, both the metal-ion oxidation state and coordination sphere could change during enzymatic turnover. Regardless, it is clear that metal ions that directly participate in enzymatic catalysis must possess dynamic coordination environments.

3.2 Mammalian Iron Enzymes

With few exceptions (certain lactobacilli), all forms of life require iron as a biocatalyst. However, only small amounts are needed – a healthy 70-kg human adult possesses just 4 g of the metal. Most of the body's iron is found in hemoglobin and ferritin; taken together, the body's iron enzymes contain less than 300 mg of iron. The common oxidation states are 2+ and 3+; higher oxidation states are known to be operative during the turnover of some iron enzymes. The widespread occurrence of iron–porphyrin prosthetic groups, or hemes, in biology has prompted the subdivision of iron enzymes into nonheme iron and heme classes.

Nonheme iron enzymes, in turn, could be classified as mononuclear iron, binuclear iron, or iron–sulfur enzymes. Table 2 lists some of these enzymes that have been found in humans, together with the reactions catalyzed and metal contents. Iron can evidently be used to catalyze both redox and acid–base reactions. Unfortunately, the active site structures of the intermediates present during turnover are not yet well understood for many of these enzymes.

A representation, partly derived from an X-ray crystallographic analysis, of the active site of pig heart mitochondrial aconitase is displayed in Fig. 2. This iron–sulfur enzyme plays a key role in the Krebs cycle, where it catalyzes the isomerization, via a *cis*-aconitate intermediate, of citrate to isocitrate. Spectroscopic and X-ray diffraction experiments have convincingly shown that the substrate directly binds to the iron–sulfur cluster during enzyme turnover. Replacement of the Ser residue depicted in the figure with Ala does not alter binding of citrate, and X-ray structures indicate that the isomerization likely proceeds via a 180° inversion of *cis*-aconitate about the $C_\alpha - C_\beta$ bond.

Several nonheme iron enzymes play important roles in the metabolism of the

Tab. 2 Representative human nonheme iron enzymes.

Enzyme	***Reaction Catalyzed***
Aconitase (Fe_4S_4)	Citrate $\rightleftharpoons$ isocitrate
Homogentisate dioxygenase (Fe)	Homogentisate $\longrightarrow$ maleylacetoacetate
Lipoxygenase (Fe)	Unsaturated fatty acids $\longrightarrow$ conjugated fatty acid hydroperoxides
Phenylalanine hydroxylase[a] (Fe)	L-Phe $\longrightarrow$ L-Tyr
Purple acid phosphatases (Fe_2)	Phosphate monoester hydrolysis
Tryptophan hydroxylase[a] (Fe)	L-Trp $\longrightarrow$ 5-hydroxy-L-Trp

[a]Also uses a tetrahydrobiopterin as an active-site cofactor.

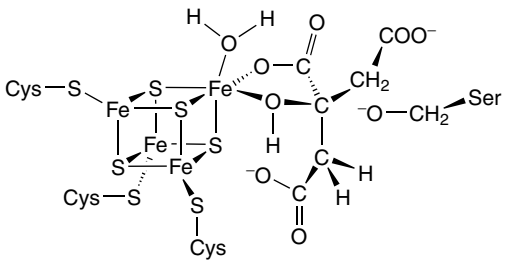

Fig. 2 Proposed structure of citrate bound to the active-site iron–sulfur cluster of pig heart mitochondrial aconitase.

aromatic amino acids phenylalanine, tyrosine, and tryptophan. These enzymes use nonheme iron and tetrahydrobiopterin (as redox cofactors) and O_2 in catalyzing regiospecific hydroxylations of these amino acids. Disfunctions in these enzymatic activities have been correlated with severe disorders, including phenylketonuria and psychiatric conditions attributed to altered serotonergic/dopaminergic neurotransmission. The mechanisms of these enzymes are believed to involve novel Fe^{2+}-O-O-pterin intermediates that heterolytically cleave to produce highly reactive Fe^{4+}=O species that subsequently oxidize substrates bound nearby.

Heme proteins figure prominently in biochemistry – their functions include electron transfer, O_2 transport, O_2 activation, and H_2O_2 activation. The latter two functions are associated with several major subclasses of oxidoreductases: oxidases, oxygenases, peroxidases, and catalases. While such activities can also be displayed by enzymes containing nonheme iron, copper, manganese, or even vanadium, it has long been evident that the use of heme cofactors in dioxygen and peroxide metabolism overshadows other alternatives in eukaryotes. Representative heme enzymes of relevance to human physiology are set out in Table 3.

All heme enzymes share one notable feature: during turnover, an oxidized intermediate (oxoferryl iron) is formed from the reaction of peroxide bound to Fe^{3+}. Two-electron reduction of dioxygen yields peroxide; not surprisingly, oxoferryl species can also be generated using O_2 and additional reducing equivalents. Catalases are unique in that H_2O_2 functions as both donor and acceptor of electrons.

Cytochromes P-450 constitute a family of heme enzymes that comprise

Tab. 3 Representative human heme enzymes.

Enzyme	***Reaction Catalyzed***
Catalase	$2H_2O_2 \longrightarrow 2H_2O + O_2$
Cytochrome *c* oxidase[a]	$O_2 + 4H^+ + 4e^+ \longrightarrow 2H_2O$; ''proton pumping''
Cytochrome *c* peroxidase	$H_2O_2 + 2H^+ + 2e^- \longrightarrow 2H_2O$
Cytochromes[b] P-450	$RH + 2e^- + O_2 + 2H^+ \longrightarrow ROH + H_2O$
Lactoperoxidase	$H_2O_2 + I^- \longrightarrow H_2O + IO^-$; others
Myeloperoxidase	$H_2O_2 + Cl^- \longrightarrow OCl^- + H_2O$
Nitric oxide synthase[c]	L-Arg $+ 2O_2 + 2H^+ + 3e^- \longrightarrow$ L-citrulline $+ 2H_2O + {}^{\bullet}NO$
Prostaglandin H synthase	Arachidonic acid $+ O_2 \longrightarrow PGH_2$
Thromboxane synthase	$PGH_2 \longrightarrow$ thromboxane A_2 + malondialdehyde + hydroxyheptadecatrienoic acid
Thyroid peroxidase	L-Tyr $+ I^- + H_2O_2 \longrightarrow H_2O + OH^-$ + monoiodotyrosine; others
Tryptophan oxygenase	L-Trp $+ O_2 \longrightarrow$ formylkynurinine

[a]Also contains active-site Cu_B, and noncatalytic metals (heme *a* and Cu_A redox centers, Na^+, Mg^{2+}, Zn^{2+}).
[b]A broad family of heme enzymes.
[c]Also uses a tetrahydrobiopterin as an active-site cofactor.

as many as 200 members in humans alone. Their roles in drug and steroid metabolism, as well as the activation of potential cancer-causing aromatic hydrocarbons, have led to their present status as the most intensely studied enzyme family. A particularly fascinating aspect of cytochrome P-450 biochemistry involves genetic (transcriptional) regulation – potential substrates can also serve as inducers *in vivo*.

Although the mammalian microsomal P-450's are of great clinical interest; they have proven difficult to purify and characterize in detail. Studies using a soluble cytochrome P-450 from *Pseudomonas putida* have led to the formulation of a detailed mechanism of P-450 enzyme action that remains the ''benchmark'' against which mechanistic features of other cytochromes P-450 are still compared. The availability of a crystal structure of the cytochrome P-450_{cam}–camphor complex affords an unusual opportunity to inspect the active site of a metalloenzyme–substrate complex (Fig. 3). What is evident from this structure is the clear origin of the regiospecific hydroxylation of the camphor substrate. The metal cofactor (heme) produces the oxidizing moiety, while the substrate-binding pocket restricts the orientation of the substrate vis-à-vis the heme iron and hence dictates *where* the substrate is hydroxylated. Recent studies on cytochrome P-450 mutants, having single mutations in the substrate-binding pocket, reinforce this view.

As indicated in Fig. 4, the ferric ''resting'' enzyme is inactive. Reduction of the heme to the ferrous state is required prior to O_2 binding; the necessary reducing equivalents taken up during enzyme turnover are supplied, via a series of electron carriers, by NADH. The key enzyme intermediate contains iron, in a formally 4+ oxidation state, and a porphyrin radical cation – this oxoferryl species oxidizes the bound substrate to form the

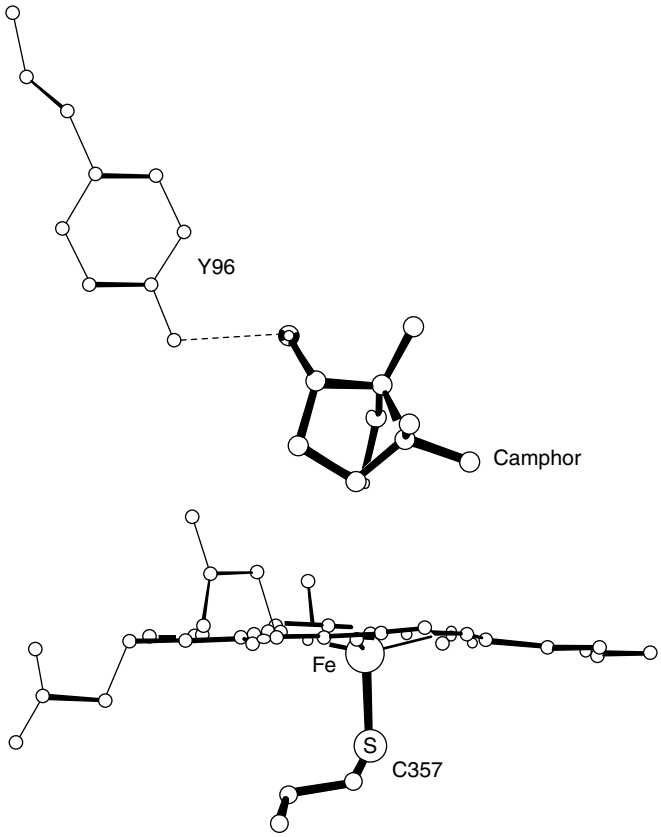

Fig. 3 Structure of the *Pseudomonas putida* cytochrome P-450$_{cam}$ active site. The substrate, camphor, is shown complexed to the enzyme, but does not coordinate to the iron.

corresponding alcohol product. The other oxygen atom from dioxygen dissociates as water; hence, all cytochromes P-450 are monooxygenases.

3.3 Mammalian Copper Enzymes

Copper ions have been found in dioxygen carriers, electron carriers, oxidases, superoxide dismutases, and oxygenases. Thus, copper and iron could be viewed as ''cousins'' insofar as their biological roles are concerned. Copper ions in biology evidently use just two oxidation states, 1+ and 2+; there is no compelling evidence for Cu^{3+} in any enzyme. Thus, catalysis of multielectron redox reactions requires more than one copper ion, or an additional redox unit – a tetrahydrobiopterin or 6-hydroxydopa quinone, for example.

Human copper enzymes (Table 4) are receiving increasing attention as a result of a growing awareness of their linkages to pathological conditions such as diabetes, cardiovascular disorders, and Alzheimer's disease. Serum amine oxidases catalyze the oxidative deamination of primary amines via a ping-pong mechanism composed of oxidative and reductive

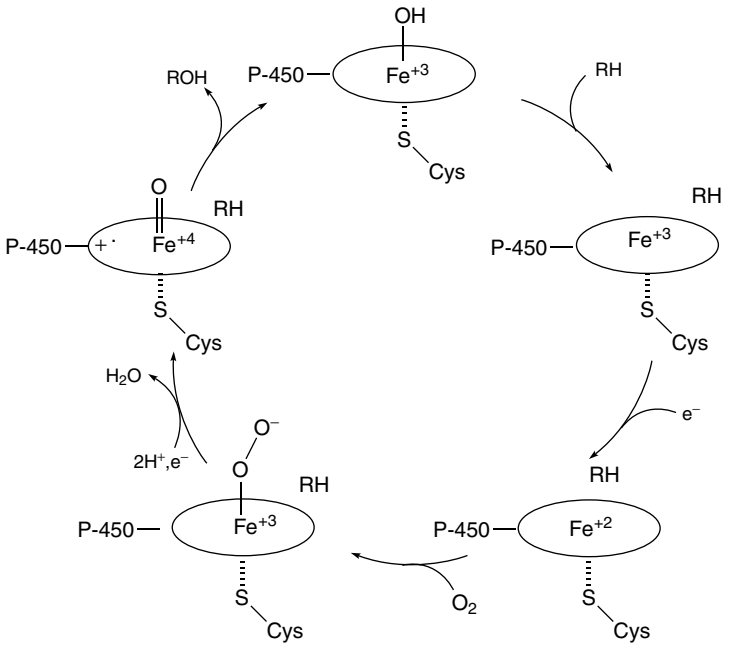

Fig. 4 Cytochrome P-450$_{cam}$ catalytic cycle. The substrate is designated as RH. Electrons are delivered to the heme in two discrete steps, the second of which is believed to limit the enzyme turnover rate.

Tab. 4 Representative human copper enzymes.

Enzyme	***Reaction Catalyzed***
Ceruloplasmin	Fe(II) $\longrightarrow$ Fe(III); other oxidations; oxidase activity
Dopamine β-hydroxylase	Dopamine $\longrightarrow$ norepinephrine
Hephaestin	Fe(II) $\longrightarrow$ Fe(III); oxidase activity
Peptidylglycine α-amidating monooxygenase	P-NH-C-COO$^-$ + O_2 + 2H$^+$ + 2e$^-$ $\longrightarrow$ P-NH$_2$ + H(CO)COO$^-$ + H_2O
Serum amine oxidase[b] B	$RCH_2NH_2^a + O_2 + H_2O \longrightarrow RCHO + H_2O_2 + NH_3$
Superoxide dismutase[c]	$2O_2^- + 2H^+ \longrightarrow O_2 + H_2O_2$

[a]Arylalkylamine substrates include serotonin and dopamine.
[b]Also uses topa quinone as a cofactor.
[c]The role of the active-site zinc is structural, rather than catalytic.

half-reactions (Eqs. 2a and 2b):

$$E_{ox} + RCH_2NH_2 \longrightarrow E_{red}\text{-}NH_2 + RCHO \quad (2a)$$

$$E_{red}\text{-}NH_2 + O_2 + H_2O \longrightarrow E_{ox} + NH_3 + H_2O_2 \quad (2b)$$

These enzymes are dimeric, having one copper ion and one covalently

bound cofactor, topa quinone (2,4,5-trihydroxyphenylalaninequinone) per monomer. Topa quinone is posttranslationally produced from a tyrosine residue during a multistep process involving the nearby copper ion and O_2. The Cu^{2+} active-site geometry in the resting enzyme is approximately square pyramidal, consisting of three histidine and two water ligands. In the reductive half-reaction (2a), a covalent bond (Schiff base complex) is formed between the substrate and topa quinone; chromophoric adducts of this type have been trapped and studied in detail. Hydrolysis of this adduct generates the aldehyde product and an E_{red}-NH_2, containing an aminoquinol form of topa quinone. Mechanistic details of the oxidative half-reaction (2b) are uncertain, and there is no unambiguous proof for redox cycling between Cu^{2+} and Cu^{1+} during enzyme turnover.

Also of intense interest is Cu,Zn superoxide dismutase (SOD), a catalyst for the disproportionation (Eq. 3) of the toxic superoxide anion:

$$2O_2^- + 2H^+ \longrightarrow O_2 + H_2O_2 \qquad (3)$$

X-ray crystal structures of the oxidized bovine erythrocyte enzyme reveal a binuclear active site: four histidine residues and a water molecule coordinate to the Cu^{2+}, while the Zn^{2+} is coordinated to three histidine and one aspartic acid. A bridging imidazolate, provided by His-61, holds the metal ions 6 Å apart. The role of the zinc appears to be structural; replacement of the Zn^{2+} by Co^{2+}, a redox-inactive spectroscopic probe, has been used to study active site changes that occur upon reduction of Cu^{2+} to Cu^{1+}. The copper bond to the imidazolate bridge is cleaved upon reduction, while the Co^{2+} bond to the bridge is retained. Subsequent X-ray crystal structures of the reduced native enzyme and mutants have confirmed this view. These observations have been incorporated into a catalytic mechanism that is illustrated in Fig. 5.

The accepted Cu,Zn SOD mechanism involves two phases: reduction of Cu^{2+} to Cu^{1+} (accompanied by liberation of O_2) and then oxidation of Cu^{1+} to Cu^{2+} (releasing hydrogen peroxide). During turnover, His-61 breaks and then reforms its bond to the active-site copper ion (there are no significant changes in Zn^{2+} geometry); these steps account for the ability of superoxide to act as both an oxidant and reductant during enzyme turnover. Situated on the rim of a deep channel, positively charged Arg-141 facilitates the catalysis by electrostatically steering and docking superoxide anions to the copper ion. Superoxide binding occurs at specific rates of ca. 2×10^9 $M^{-1}s^{-1}$, very near the limit of diffusion control.

3.4 Mammalian Zinc Enzymes

In 1939, Mann and Keilin discovered zinc in carbonic anhydrase, an enzyme whose function is to catalyze the hydration of carbon dioxide to the more soluble bicarbonate anion. Since that time, hundreds of zinc enzymes have been discovered; X-ray structures for dozens of these are now available. Table 5 lists some of the known human zinc enzymes, together with their activities. Divalent zinc plays a particularly conspicuous role in hydrolytic and group transfer biochemistry. Zinc is an excellent choice for such tasks because it is redox-inactive, easily exchanges ligands, and forms four-, five-, and six-coordinate complexes of comparable stability. Catalytic zinc sites always contain several endogenous (i.e. protein-derived) ligands and coordinated water.

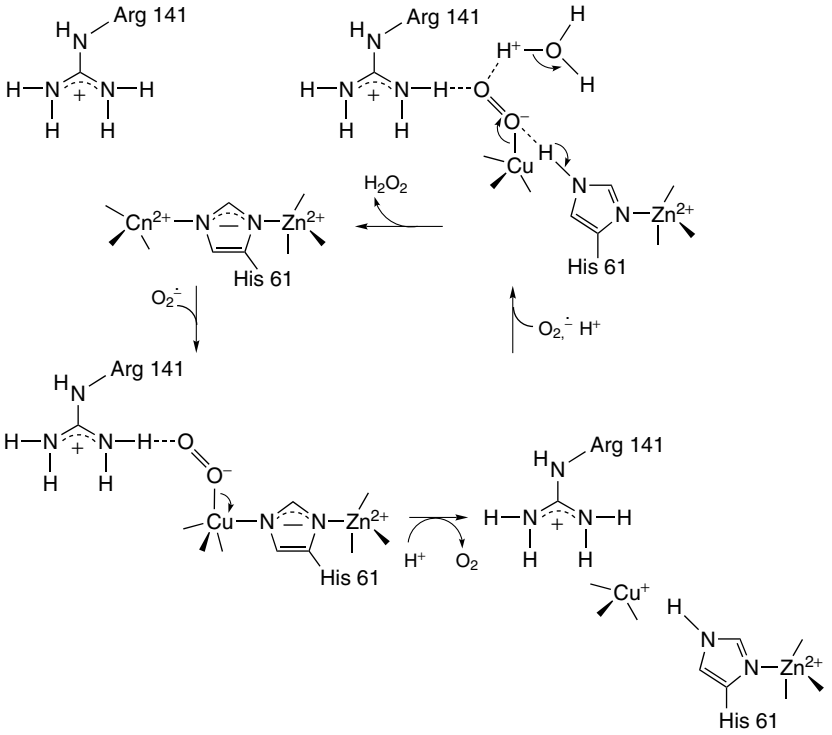

Fig. 5 Proposed mechanism of action of bovine erythrocyte Cu,Zn superoxide dismutase. The copper ion is involved in the catalysis, whereas the zinc plays a purely structural role.

Tab. 5 Representative human zinc enzymes.

Enzyme	***Reaction Catalyzed***
Alcohol dehydrogenase	$RR'CHOH + NAD^+ \longrightarrow RR'C{=}O + NADH + H^+$
Carbonic anhydrase	$CO_2 + H_2O \rightleftharpoons HCO_3^- + H^+$
Carboxypeptidases	C-terminal peptide bond hydrolysis
Glutaminyl cyclase	N-terminal Gln $\longrightarrow$ N-terminal pyroGlu + NH_3
Phospholipase C	Phospholipid hydrolysis
Ribonuclease A	RNA digestion (products contain 3′-phosphate termini)
RNA polymerase I	RNA biosynthesis (transcriptional elongation)
Stromelysin[a]	Peptide bond hydrolysis (ECM proteins)

[a]Also contains three noncatalytic Ca^{2+} ions.

The most important reactivity feature of divalent zinc is its Lewis acidity – it can polarize bound ligands and increase their susceptibility to attack by external nucleophiles or even increase the attacking power of a coordinated base. Water molecules coordinated to Zn^{2+} can deprotonate to form coordinated hydroxide

at neutral pH. Alternatively, displacement of the coordinated water by a substrate could lead to electrophilic catalysis.

Human carbonic anhydrase II catalyzes the *reversible* hydration of CO_2 in several distinct phases, where A represents a proton-transfer relay in which a proton is believed to reach His-64 before one transfers to the solvent:

$$EZNOH^- + CO_2 \longleftrightarrow EZnHCO_3^- \quad (4a)$$

$$EZnHCO_3^- + H_2O \longleftrightarrow EznH_2O + HCO_3^- \quad (4b)$$

$$EznH_2O + A \longleftrightarrow EznOH^- + AH^+ \quad (4c)$$

The kinetics of the carbonic anhydrase reaction increase with increasing pH, and display a sigmoidal pH-activity profile (apparent pK_a of ca. 7.0). It is now agreed that this reflects the deprotonation of coordinated water (by Thr-199) to produce a zinc-bound hydroxide ion, as indicated in Fig. 6. Thr-199 may also stabilize the transition state of the reaction through a hydrogen bond, and proline substitution at this position reduces catalytic efficiency by a factor of 3000. Further support for the proposed cycle in the figure comes from X-ray crystal structures of bicarbonate complexes of the Zn^{2+} and Co^{2+} enzymes. Bicarbonate is a monodentate ligand in both structures. However, water is also bound to the metal in the Co^{2+} enzyme–substrate complex, indicating that a five-coordinate metal intermediate in the native enzyme in solution is possible.

Carboxypeptidase A has also been the subject of intense mechanistic scrutiny. Glu-270 appears to abstract a proton from

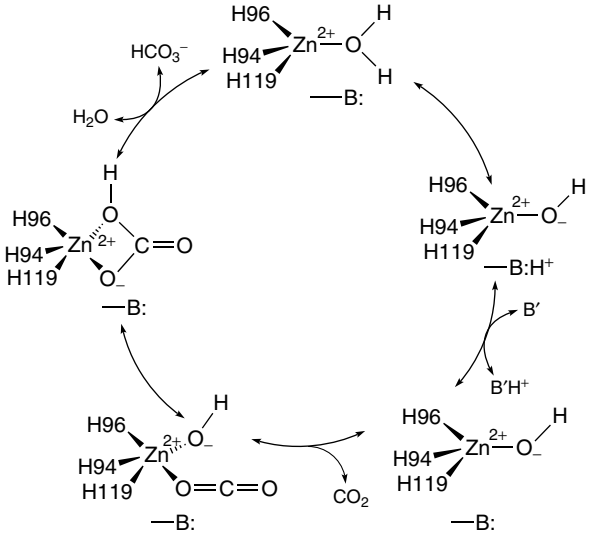

Fig. 6 Proposed mechanism for human carbonic anhydrase II. Basic side chains (B & B′) assist the zinc ion in forming coordinated hydroxide, which attacks coordinated CO_2 to form an anhydride intermediate. Residue B, likely Thr-199, performs a ''gatekeeper'' function.

the Zn^{2+}-coordinated water to produce the nucleophile needed to attack a backbone carbonyl of the substrate. A nearby side chain, Arg-127, activates the carbonyl group of the scissile peptide bond, facilitating the attack of coordinated hydroxide to produce a tetrahedral intermediate. This intermediate then coordinates to the zinc to produce a five-coordinate complex, which subsequently collapses to produce the products (two peptide fragments).

Many other zinc-catalyzed hydrolytic reactions are believed to proceed via the use of coordinated hydroxide. Matrix metalloproteases (MMPs) constitute a large family of mononuclear zinc endoproteases that are involved in the degradation of collagen, fibronectin, laminin, and other components of the extracellular matrix of connective tissue. They are important medicinal targets because uncontrolled MMP activity can lead to pathological conditions that include osteoarthritis, rheumatoid arthritis, and tumor invasion. Most MMPs share the consensus sequence HEXXHXXGXXH, in which the Zn^{2+} is coordinated to the three histidine residues. Substrates (which may include peptide loops of other enzyme molecules), inhibitors, and H_2O/OH^- molecules, can provide the fourth (or possibly a fifth) ligand.

Other human zinc enzymes contain more complex active sites involving more than one metal ion in the catalysis. This is thought to occur in renal dipeptidase-catalyzed reactions, for example. For this enzyme, a step involving binding of the dipeptide substrate by one of the two active-site zinc ions has been suggested on the basis of an X-ray structure, while the second zinc ion generates the coordinated hydroxide that catalyzes the hydrolytic reaction. Alkaline phosphatases contain two Zn^{2+} and one Mg^{2+} arranged in an active-site cluster whose molecular mechanism of action remains uncertain.

3.5 Mammalian Cytochrome *c* Oxidase

The redox chemistry catalyzed by heme enzymes includes respiratory dioxygen reduction. This reaction is catalyzed by cytochrome *c* oxidase, a complex membrane enzyme, consisting of 13 different polypeptides, that contains heme and copper centers at the dioxygen binding site, for the purpose of vectorially translocating protons across the inner mitochondrial membrane. The resulting proton gradient is then used by ATP synthase to catalyze ATP synthesis from ADP and phosphate. The bovine heart enzyme is the best studied of all of the cytochrome *c* oxidases, having been the subject of intense study in numerous laboratories for more than 70 years. For decades, there was a great deal of controversy concerning even the most basic information – the enzyme's metal content. Purification is extremely difficult, because of the multisubunit nature of this enzyme, and this has contributed to conflicting experimental results. During the last decade, Shinya Yoshikawa and coworkers have successfully crystallized the bovine heart enzyme and produced medium/low-resolution (2.3–2.9 Å) X-ray structures of four forms of the enzyme, including azide- and carbon monoxide-bound derivatives, while Hartmut Michel and coworkers produced X-ray structures of a bacterial cyrochrome *c* oxidase from *Paracoccus denitrificans*. These structures have clarified many controversial issues, and are guiding ongoing work on enzyme mutants and refinements of spectroscopic assignments.

Cytochrome *c* oxidase contains an unusual type of solvent-extractable heme cofactor, designated an *a*-type heme in contrast to the more familiar *b*-type heme found in hemoglobin and heme peroxidases (Fig. 7). Redox-active copper ions are also present, as well as sodium, zinc, and magnesium ions that appear to serve structural roles. Two of the redox cofactors, designated heme *a* and Cu_A, are believed to serve as electron-transfer agents, linking electron flow between the physiological reductant, cytochrome *c*, and the active site of the enzyme. Discrete cytochrome c^{red}-binding events are needed to transfer electrons to the fully oxidized enzyme, enabling it to catalyze the four-electron reduction of one O_2 molecule to two water molecules. Figure 8 displays a simplified view of the active site, which contains heme a_3 and Cu_B separated by ca. 5 Å. The X-ray structures revealed a surprising cross-link between Tyr-244 and His-240 that is of unknown origin, but is reminiscent of other cross-links found in copper enzymes like galactose oxidase. Another peculiar feature of the X-ray structures is the lack of an obvious channel for passage

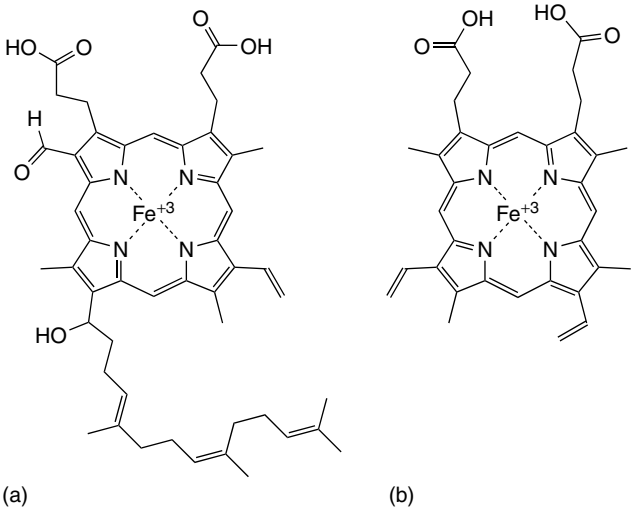

Fig. 7 Structures of active-site heme groups found in human metalloenzymes: (a) heme a_3 and (b) heme *b*.

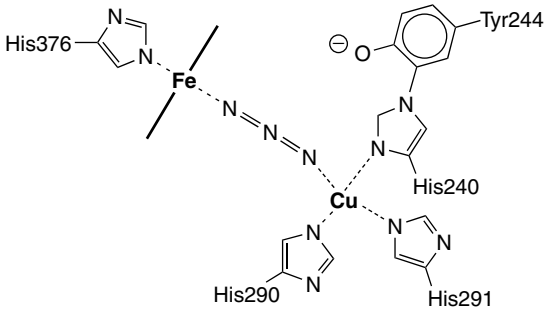

Fig. 8 Simplified cartoon of the binuclear active site of bovine cytochrome *c* oxidase, showing azide ion bound to both heme a_3 and Cu_B. Tyr-244 and His-240 are cross-linked, a result of a posttranslational self-processing event.

of O_2 to the binuclear active site during enzyme turnover, reinforcing the importance of protein fluctuations in the mechanism of action of cytochrome *c* oxidase.

While it is generally agreed that this heme a_3-Cu_B site is the active site for O_2 reduction, the details of this process remain unclear. Small molecules like azide and cyanide stabilize the active-site Fe(III)-Cu(II) oxidation states, locking the enzyme into a conformation that cannot react with O_2, and this is the molecular origin of the toxicities of these anions (the result is heart failure once the heart mitochondria begin to run out of ATP). CO, on the other hand, stabilizes the active-site Fe(II)-Cu(I) oxidation states, making another enzyme conformation amenable to study, and provides ready access to unstable intermediates when the CO adduct is photolyzed at low temperature in the presence of dissolved O_2. Resonance Raman spectroscopy has demonstrated that an early enzyme intermediate contains O_2 bound to reduced Fe_{a3}^{2+}. The X-ray structures also suggest that reduced Cu_B weakly interacts with bound O_2. Electron transfers from both metals to the bound O_2 would then produce a peroxo intermediate, long thought to be bridging Fe(III)-O-O-Cu(II). However, the X-ray structures raise the possibility of a hydrogen bond between protonated Tyr-244 and bound O_2, suggesting a peroxo intermediate that does not bind to Cu_B. Once a third electron is delivered to O_2, the O—O bond breaks, producing water (after protonation) and an oxoferryl heme a_3. Where does the third electron come from – the cross-linked Tyr-244, Cu_B^{1+}, or re-reduced heme a_3 (produced by fast electron transfer from heme *a*)? The fourth electron reduces the ferryl heme back to the ferric oxidation state, with the oxo group forming coordinated hydroxide that dissociates as water after protonation.

The mechanism of proton pumping by cytochrome *c* oxidase is even less clear because physical information, such as conserved amino acid residues or X-ray structures, cannot currently distinguish pumped protons from other dissociable protons. Hence, there has been much speculation regarding the proton pumping mechanism, particularly mechanistic proposals that link proton-translocation events to specific electron transfers.

3.6 Mammalian Enzymes Containing Less Common Metals

Much less is known about the active-site structural motifs and mechanisms of enzymes that contain metals other than iron, copper, or zinc. While most of these ''unusual'' enzymes (Table 6) are typically found in microbes and plants, there are known mammalian examples that play physiologically important roles.

Cobalt is found in vitamin B_{12}-dependent enzymes, and thus can play a role in radical reactions, as well as hydrolytic chemistry discussed earlier. There are two main roles for vitamin B_{12} (cyanocobalamin) in humans, both involving the formation of alkyl derivatives as enzyme intermediates. When cobalamin binds to its domain in nascent methionine synthase, it acquires an axial histidine ligand, which replaces benzimidazole, leaving a sixth coordination site available. The B_{12} domain of this complex enzyme must rapidly and efficiently interact with three other domains containing methyltetrahydrofolate, homocysteine, and *S*-adenosylmethionine, and methyl group transfer to form the methionine

Tab. 6 Representative human enzymes containing unusual metals.

Enzyme	*Cofactor*	*Reaction Catalyzed*
Arginase	2Mn	L-Arg + H_2O ⟶ L-ornithine + urea
Methionine aminopeptidase	2Mn	Hydrolysis of N-terminal Met residue of nascent proteins
Methylmalonyl-CoA mutase	1AdoCbl[a]	Methylmalonyl-CoA ⟶ succinyl-CoA
Secreted Phospholipases A_2	1Ca	Glycerophospholipid hydrolysis
Sulfite oxidase	1Mo-co, 1 heme/subunit	$SO_3^{2-} + H_2O \longrightarrow SO_4^{2-} + 2H^+ + 2e^-$
Superoxide dismutase	1Mn	$2O_2^- + 2H^+ \longrightarrow O_2 + H_2O_2$
Xanthine oxidase[b]	1Mo-co, $2Fe_2S_2$, 1FAD/subunit	Xanthine ⟶ uric acid

[a] 5-Adenosylcobalamin.
[b] Can catalyze other reactions: O_2^- generation from O_2, and NO and nitrite production from nitrate during anoxia.

and tetrahydrofolate products is catalyzed by an intermediary methylcobalamin complex (Co^{3+}). During catalysis, the cobalt cycles between Co^{3+} and Co^{1+}. A minor Co^{2+} form can appear as a result of oxidative processes, which must be reduced back to Co^{1+} to reactivate the enzyme.

The 5-deoxyadenosyl adduct of cobalamin is the most abundant derivative of vitamin B_{12} in the liver, and is required for the catabolism of some branched-chain amino acids (using methylmalonyl-CoA mutase to generate succinyl-CoA from methylmalonyl-CoA). Deficiencies in this vitamin B_{12}, while rare, include neurologic disorders attributed to demyelination of nervous tissue. Succinyl-CoA formation occurs via an enzyme-catalyzed isomerization, rather than the methyl transfer process discussed above:

$$\text{CoA-SCOCH(CH}_3\text{)COOH} \longleftrightarrow \text{CoA-SCOCH}_2\text{CH}_2\text{COOH} \quad (5)$$

The CoA-SCO- is transferred intramolecularly and the hydrogen that is transferred does not exchange with water during enzyme turnover.

Three oxidation states (2+, 3+, and 4+) are commonly observed for manganese cofactors in biology, making them well suited for the catalysis of many of the reactions discussed in the section on iron enzymes. Human manganese superoxide dismutase (SOD) contains a manganese coordinated to three histidine, one aspartic acid, and one water molecule in a trigonal bipyramidal geometry. Catalysis is thought to proceed via the following scheme:

$$\text{Mn(III)SOD} + O_2^- + H^+ \longrightarrow \text{Mn(II)SOD}(H^+) + O_2 \quad (6a)$$

$$\text{Mn(II)SOD}(H^+) + O_2^- + H^+ \longrightarrow \text{Mn(III)SOD} + H_2O_2 \quad (6b)$$

$$\text{Mn(II)SOD}(H^+) + O_2^- \longrightarrow \text{Mn(III)}(O_2^{2-})\text{SOD}(H^+) \quad (6c)$$

$$\text{Mn(III)}(O_2^{2-})\text{SOD}(H^+) + H^+ \longrightarrow \text{Mn(III)SOD} + H_2O_2 \quad (6d)$$

Steps (6c) and (6d) represent the formation and dissociation of a product-inhibited complex. Gln-143 is hydrogen-bonded to the coordinated water and this residue that is essential for the high activity of the enzyme (minimizing steps (6c) and (6d), which involve a presumed, intermediary peroxo complex).

Liver arginase I contains a binuclear manganese center (ca. 3.3 Å Mn–Mn distance), catalyzing the hydrolysis of L-arginine to form L-ornithine and urea. This reaction is the final cytosolic step of the urea cycle. It is generally agreed that both Mn^{2+} ions orient and polarize a bridging hydroxide, which attacks the guanidinium carbon of the arginine substrate (held in place by Asp-277 and His-141). An isozyme, arginase II, is found in nonhepatic tissues (e.g. gastrointestinal smooth muscle, penile corpus cavernosum smooth muscle), where it facilitates the regulation of NO biosynthesis by attenuating the levels of L-arginine available to nitric oxide synthase (a heme enzyme):

$$\text{Arginase I/II : L-arginine} \longrightarrow \text{L-ornithine} + \text{urea} \quad (7)$$

$$\text{NO synthase : L-arginine} \longrightarrow \text{L-citrulline} + \text{NO} \quad (8)$$

The latter process proceeds via an N^{ω}-hydroxy-L-arginine intermediate, which is itself a modest, competitive inhibitor of arginase.

Molybdenum is a moderately important element – it is found in nitrogenase, a variety of bacterial enzymes, and several mammalian enzymes (sulfite oxidase, aldehyde oxidase, and xanthine oxidase). Molybdoenzymes are large and typically contain other cofactors as well. Rather surprisingly, since oxides (e.g. MoO_4^{2-}) are found in aqueous solutions, the molybdenum centers are usually in sulfur-rich environments (see Fig. 1). Most molybdoenzymes hydroxylate their substrates, yet are not classified as oxygenases because they transfer oxo ligands that are *not* derived from O_2.

Mitochondrial sulfite oxidase is responsible for the oxidation of sulfite (SO_3^{2-}) to sulfate (SO_4^{2-}) and has been studied in detail. This enzyme catalyzes the final reaction in the catabolism of sulfur-containing amino acids. Each enzyme monomer has domains for the molybdenum-pterin cofactor (Mo-co), bound to the polypeptide via a cysteine ligand, and for a cytochrome b_5 (an electron-transfer center, represented as iron in the scheme below). The overall reaction can be viewed in terms of the following events:

$$\text{Mo(VI),Fe(II)} + \text{cyt } c^{\text{ox}} \longrightarrow \text{Mo(VI),Fe(III)} + \text{cyt } c^{\text{red}} \quad (9a)$$

$$\text{Mo(VI),Fe(III)} + SO_3^{2-} \longrightarrow \text{Mo(IV),Fe(III)} + SO_4^{2-} + 2H^+ \quad (9b)$$

$$\text{Mo(IV),Fe(III)} \longrightarrow \text{Mo(V),Fe(II)} \quad (9c)$$

$$\text{Mo(V),Fe(II)} + \text{cyt } c^{\text{ox}} \longrightarrow \text{Mo(V),Fe(III)} + \text{cyt } c^{\text{red}} \quad (9d)$$

$$\text{Mo(V),Fe(III)} \longrightarrow \text{Mo(VI),Fe(II)} \quad (9e)$$

In step (9b), sulfite reacts with an oxo ligand coordinated to Mo(VI), forming sulfate coordinated to Mo(IV), and hydroxide (derived from water) coordinates to the molybdenum site after departure of sulfate. The oxo ligand (deprotonated hydroxide) forms in response to formation of Mo^{6+}.

3.7
Bacterial Metalloenzymes and Their Roles in Infection

Understanding molecular mechanisms underlying microbial virulence is critically important to the development of effective antimicrobial compounds and remedies for intoxication (e.g. botulism), particularly caused by food- and water-borne bacteria. Bacteria that must survive the acidic gastric environment (e.g. *Helicobacter pylori*, *Klebsiella aerogenes*) produce enzymes that provide a source of nitrogen for growth and help neutralize the pH immediately surrounding the cell. *Klebsiella aerogenes* urease has been the most intensively studied of these, and contains two Ni^{2+} ions in the enzyme active site, separated by ca. 3.6 Å. Assembly of the binuclear Ni^{2+} active site is complex, requiring a variety of accessory proteins (including at least one nickel chaperone, UreE) *in vivo*. These ions are bridged by a lysine residue that has been carbamylated as a result of a posttranslational self-processing reaction with CO_2. *In vitro* reconstitution of the apoenzyme in the absence of CO_2 does not generate any urease activity. The accepted mechanism comprises a step involving urea binding to Ni-1 (carbonyl oxygen coordination), and hydrogen bonding to His-320. Hydroxide coordinated to Ni-2 attacks the carbonyl carbon to form a tetrahedral intermediate. His-320 transfers a proton to an amide nitrogen of the urea intermediate, which then collapses into ammonia and carbamate (H_2NCOOH). The carbamate product is itself unstable, and spontaneously decomposes to form CO_2 and a second ammonia molecule. The net result of the urease-catalyzed and uncatalyzed reactions is the following:

$$CO(NH_2)_2 + H_2O \longrightarrow 2NH_3 + CO_2 \quad (10)$$

One host defense strategy involves the production of IgA molecules that bind to both bacterial surface antigens and mucin, trapping the invading bacterial cells in the mucin. Some strains of pathogenic bacteria (particularly streptococci) secrete a variety of zinc metalloproteases, including enzymes (IgA1 proteases) that cleave human IgA1 in the hinge region. These proteases all possess one Zn^{2+} ion coordinated to two histidine and one glutamic acid

Tab. 7 Representative bacterial metalloenzymes of medical importance.

Enzyme	*Cofactor*	*Reaction Catalyzed*
Botulinum toxin	1Zn	Peptide bond hydrolysis (long substrates[a], specific cleavages)

residue, with the remaining site occupied by hydroxide.

The causative agent of anthrax, *Bacillus anthracis*, produces a variety of secreted toxins, one of which (lethal toxin) is the primary cause of death in infected animals and is considered a key virulence factor. Lethal toxin consists of protective antigen and lethal factor, which is a zinc metalloprotease that cleaves members of themitogen-activated protein-kinase–kinase (MAPKK) family near their amino-termini. The X-ray structure of lethal factor shows that the Zn^{2+} is coordinated to His-686, His-690, Glu-735 and a water/hydroxide molecule in an approximately tetrahedral geometry. Glu-687 is positioned ca. 3.5 Å from the coordinated water to act as a proton acceptor and facilitate the formation of coordinated hydroxide. The active site of lethal factor is contiguous with a 40-Å long groove that serves as the substrate-binding pocket. The specificity for MAPKK substrates arises in primarily from this binding site, rather than the zinc site.

Botulism and tetanus are caused by Gram-positive, spore-forming bacteria (*Clostridium botulinum* and *Clostridium tetani* respectively) that require near-anaerobic conditions for growth. These organisms secrete dangerous toxins that are frequently fatal (death results from intoxication rather than infection *per se*). The toxins responsible for the symptoms are zinc metalloproteases that cleave proteins that are associated with neurotransmitter release. Strains of toxigenic *C. botulinum* produce a variety of antigenically distinct botulinum toxins, designated A, B, C1, D, E, F, and G. Botulinum toxins A, E, and C1 cleave synaptosomal-associated protein (SNAP-25) at different sites, the others (and tetanus toxin) cleave vessicle-associated membrane protein (VAMP, also known as synaptobrevin), and C1 additionally cleaves syntaxin. Types A, B, and E are the principal causes of botulism in humans. The catalytic domains contain the usual [HExxH + E] motif displayed by many other zinc endoproteases. Mature botulinum toxins are very large, composed of a heavy chain (ca. 100 kDa) and a light chain (ca. 50 kDa) that are held together by a disulfide bond. The heavy chain binds to the presynaptic membrane and helps to translocate the light chain across the membrane into the cytosol, where the light chain cleaves a VAMP/SNAP-25 target protein. Botulinum toxins, particularly type A toxins, are considered the most potent toxins known. Once a botulinum toxin A molecule enters the neuronal cytosol, it is estimated that a single enzyme molecule is sufficient to intoxicate a synapse.

The zinc active site is deeply buried in botulinum toxins, and is accessible to the solvent via a ca. 12 Å × 15 Å × 35 Å channel. The clostridial neurotoxins are atypical among zinc metalloproteases because of their stringent substrate specificities (substrates must be at least 16 amino acids in length, and cleavage is site-specific). The catalytic mechanism of the all of these toxins appears to involve formation of zinc-coordinated hydroxide, polarization of a carbonyl (amide) group of the substrate by a nearby amino acid residue, hydrogen bonding of an additional nearby residue to the amide nitrogen, and collapse to form the product peptides. Botulinum toxin A has been shown to form a dimer in aqueous solution at concentrations above 75 nM (the enzyme is a monomer in crystals studied to date). Endopeptidase activity is inhibited by 75% when the dimer

forms, suggesting that substrate access to the channel is sterically restricted in the dimer.

4 Perspectives

In addition to the metals mentioned in this article, roles for other metals as enzyme cofactors will undoubtedly be elucidated in the near future. One fascinating, and perplexing, feature of biological systems concerns the rationale for the selection of a particular metal cofactor for a given biological task. Consider the superoxide dismutases. Four different kinds of enzyme active sites have been discovered in various prokaryotes and eukaryotes, containing either mononuclear iron, mononuclear manganese, a binuclear Cu,Zn dimer, or mononuclear nickel (in some bacteria). Why do all forms of life not use just one type of cofactor? Why are specialized kinds of human superoxide dismutases needed (an intracellular manganese enzyme, an intracellular Cu,Zn enzyme, and an extracellular Cu,Zn enzyme)?

As noted earlier in this article, many redox enzymes utilize O_2 or H_2O_2 as the source of oxidizing equivalents needed to hydroxylate a substrate. In particular, iron-peroxo or iron-oxo intermediates have been proposed for most iron enzymes discussed in this chapter. What keeps these kinds of enzymes from inactivating (self-destructing) during enzymatic turnover, a result of repeated oxidation of nearby amino acid residues or production of radicals that tunnel and carry out redox transformations elsewhere in the enzyme? Both hemoglobin and myoglobin function as O_2 carriers, but can also react with H_2O_2 and organic substrates in peroxidase-like fashion. Unlike peroxidases, the globins rapidly lose enzyme activity during turnover because their Compound I intermediates are unstable, ultimately destroying the heme chromophores, and forming protein oligomers. What are the structural constraints for a good heme peroxidase? Similar stability problems are posed by other broad classes of redox enzymes.

New, clinically important, roles for small-molecule interactions with metalloenzymes continue to emerge. For example, the gases NO and CO, both vertebrate hormones, are generated by metalloenzymes. Furthermore, some target cell responses to these gases are the result of binding to other metalloenzymes (e.g. NO binding to the heme enzyme guanylyl cyclase causes a large conformational change that results in a ca. 300-fold increase in activity). Many therapeutic drugs target metalloenzymes. Prominent examples include nonsteroidal anti-inflammatory drugs, such as aspirin or indomethacin. These drugs block prostaglandin production by inhibiting a heme enzyme, prostaglandin H synthase.

Many clinically important roles for enzyme oligomerization and folding pathways involving metalloproteins are only beginning to be understood. For example, mutations in the structural gene SOD1, encoding a Cu,Zn superoxide dismutase, figure prominently in current research on the molecular origins of amylotropic lateral sclerosis (ALS). Some mutant enzymes cannot tightly bind active-site metal ions, their apo-forms are partially unfolded, and are hence more likely to form insoluble aggregates.

Finally, it is important to note that copper ions have been shown to play key roles in posttranslational self-processing,

leading to the production of new, covalently bound redox centers (thus far only known to be derived from endogenous tyrosine residues in the active site). Additional cases of this phenomenon are to be expected, with important mechanistic implications.

Keywords

Domain
A phylogenetic taxon that is higher than the level of kingdom and is based on the classification of organisms according to similarities in 16S ribosomal RNA sequences. The current phylogenetic classification scheme divides organisms into three domains: the Archaea, Bacteria, and Eucarya.

Domain Archaea (Formerly Archaebacteria)
The domain composed of prokaryotic microorganisms with archaeal-type ribosomal RNA. Archaeal cellular membranes typically contain lipids with glycerol diether or diglycerol tetraether linkages. The domain Archaea consists of three phenotypic groups (methane producers, extreme halophiles, and sulfur-dependent extreme thermophiles), but it is formally divided into four kingdoms: the Euryarchaeota, Crenarchaeota, Korarchaeota, and Nanoarchaeota.

Domain Bacteria (Formerly Eubacteria)
The domain composed of prokaryotic microorganisms with bacterial-type ribosomal RNA. Bacterial cellular membranes contain lipids with glycerol diester linkages.

Domain Eucarya
The domain that includes all eukaryotic organisms, characterized by eucaryotic-type 16S ribosomal RNA. Eucaryal cells contain a defined nucleus and glycerol diester cell membrane lipids.

Prokaryote
A cellular organism that lacks a true nucleus.

Although members of the domain Archaea are prokaryotic in cell structure, 16S rRNA sequencing reveals that they form a phylogenetically coherent group, which is separate from both Bacteria (Eubacteria, domain Bacteria) and eucaryotes (Eucarya, domain Eucarya). The Archaea are further distinguished by the ether-lipid composition of cytoplasmic membranes and cell wall components not found in either the Bacteria or Eucarya domains. Like in Bacteria, transcription and translation in Archaea take place in the same cellular compartment. Unlike Bacteria, Archaea

possess a complex DNA-dependent RNA polymerase and genes with promoter elements similar to the TATA box of eucaryotes. Archaea produce and utilize homologs to eukaryotic transcription-initiation factors, which are not found in the Bacteria domain. The methane-producing Archaea (methanoarchaea) are the most diverse and extensively studied group of the Archaea. The strictly anaerobic methanoarchaea are terminal organisms in the anaerobic phase of the global carbon cycle.

1 Introduction

For nearly half a century, life was classified at the highest level by two taxons, prokaryotes and eucaryotes, on the basis of phenotypic cellular characteristics that included the presence or absence of nuclear membranes, organelles, or cell walls. It was not until 1990 that a molecular approach, based on comparisons of 16S ribosomal RNA sequences, revealed that all life forms are divided into three primary divisions (domains) of life: the Eucarya, encompassing all eucaryotes, the Bacteria (or Eubacteria), including ''typical'' Eubacteria, and the Archaea (or Archaebacteria). The Archaea are comprised of four kingdoms: Euryarchaeota, Crenarchaeota, Korarchaeota, and the recently described Nanoarchaeota. In evolutionary terms, the two prokaryotic domains are more genetically distinct from each other than one of the groups, the Archaea, is from the Eucarya. The largest, most diverse, and well-studied representatives of the Archaea are the methane-producing anaerobes (methanoarchaea), which provided the first clues leading to the discovery of the three-domain concept. The methanoarchaea are members of the Euryarchaeota. Research on the methanoarchaea over the past two decades has made the greatest impact on our understanding of the ecology, physiology, and biochemistry of the Archaea. More recently, genomic sequencing, development of genetic systems, and investigations into the molecular biology of the methanoarchaea has significantly expanded our knowledge of the Archaea domain.

2 Biochemistry of Methanogenesis

The Italian physicist Alessandro Volta is most often credited with the discovery of biological methane (natural gas) production, methanogenesis, more than 125 years ago. In performing the ''Volta experiment,'' he disturbed the sediment of lake Como in northern Italy with a pole releasing the trapped methane bubbles. Lighting the gas produced a flame that he called ''combustible air.'' Figure 1 shows a modern-day Volta experiment in which gas from the sediment of a freshwater pond is collected in an inverted funnel submerged in the water column and ignited on release by tipping the funnel. The process of methanogenesis requires a consortium of at least three interacting metabolic groups of obligately anaerobic microbes (Fig. 2). The fermentative group decomposes cellulose and other complex molecules to volatile carboxylic

Fig. 1 A modern-day Volta experiment (see color plate p. xxxiv).

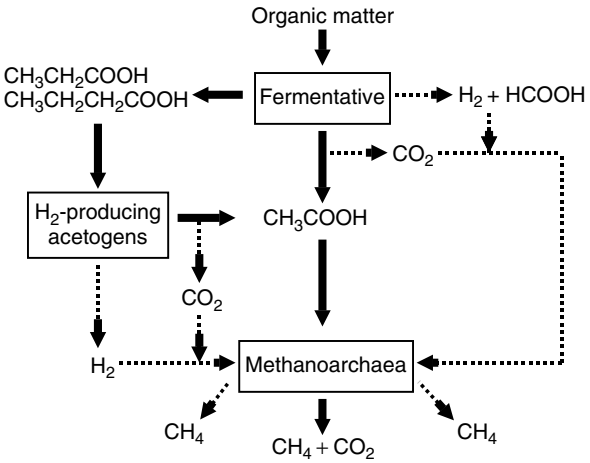

Fig. 2 A scheme showing carbon flow through the three major metabolic groups of anaerobes involved in the conversion of complex organic matter to methane in freshwater environments.

acids and hydrogen gas. Only acetate, carbon dioxide, hydrogen, and formate are the major substrates for the methanoarchaea; thus, the hydrogen-producing acetogenic group is necessary to further metabolize butyrate and propionate to substrates for the methanoarchaea. The methanoarchaea employ two separate pathways in which methane derives from either the methyl group of acetate (reaction 1) or the reduction of carbon dioxide with electrons from hydrogen or formate (reactions 2a and 2b). At least two-thirds of the total methane produced derives from the acetate and

the remainder from the reduction of carbon dioxide.

$$CH_3COO^- + H^+ \longrightarrow CH_4 + CO_2 \quad (1)$$

$$CO_2 + 4H_2 \longrightarrow CH_4 + 2H_2O \quad (2a)$$

$$4HCO_2H \longrightarrow 3CO_2 + CH_4 + 2H_2O \quad (2b)$$

2.1 Steps Common to the Two Major Pathways for Methanogenesis

The steps shown in Fig. 3 are common to the two major pathways for methane production in nature, carbon dioxide reduction and fermentation of acetate. The two pathways differ primarily in the manner by which a methyl group is generated and passed to the cofactor tetrahydromethanopterin (H_4MPT) to form CH_3-H_4MPT. Conversion of CH_3-H_4MPT to methane is essentially the same in both pathways. Step 1 in Fig. 3 is catalyzed by N^5-methyltetrahydromethanopterin:coenzyme M methyltransferase, which has been recently reviewed. The methyltransferase is an integral membrane-bound complex that also functions to generate a sodium-ion gradient across the membrane coupled to the methyl transfer reaction. The enzyme as characterized from *Methanothermobacter marburgensis* and *Methanosarcina mazei* contains a corrinoid cofactor, cobalamine (5′-hydroxybenzimidazolyl cobamide), which accepts the methyl group from CH_3-H_4MPT in the first of the two partial reactions catalyzed by the enzyme. The second partial reaction involves transfer of the methyl group from CH_3-cobalamine to coenzyme M (HS-CoM) producing CH_3-S-CoM. The methyltransferase complex contains eight nonidentical subunits (MtrA-H). MtrA contains the cobalamine cofactor protruding into the cytoplasm that undergoes methylation and demethylation. It is proposed that methylation is catalyzed by MtrH and demethylation by MtrE, which also translocates sodium ions. The mechanism of translocation is thought to involve conformational changes induced in MtrA by methylation and demethylation that are transmitted to MtrE, which drives the

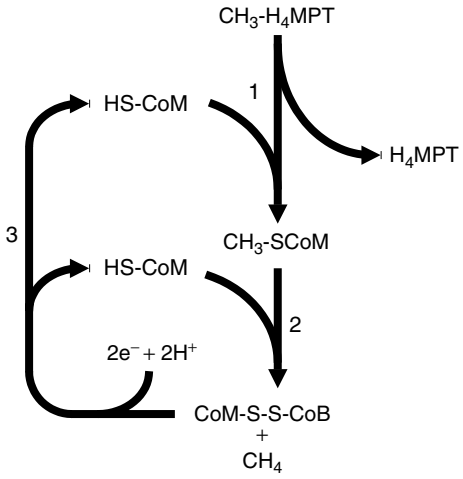

Fig. 3 Steps common to the two major pathways for methanogenesis.

translocation. Growth of the methanoarchaea utilizing either pathway is dependent on sodium and is proposed to use sodium gradients for energetic functions.

The methyl-coenzyme M-reductase catalyzes step 2 in Fig. 3. The electron donor is coenzyme B (CoB) and the heterodisulfide CoM-S-S-CoB is produced in addition to methane. *Methanothermobacter marburgensis* and *Methanothermobacter thermoautotrophicus* contain two isozymes (MCRI and MCRII) with native molecular masses of approximately 300 kDa composed of three different subunits with molecular masses of 65 (α), 46 (β), and 30–35 (γ) kDa in an $\alpha_2\beta_2\gamma_2$ configuration. The crystal structure of the MCRI isozyme from *M. marburgensis* shows coenzyme F_{430} (F_{430}) positioned at the bottom of a narrow channel in two independent active sites separated by approximately 50 Å. The two active sites are formed by residues from the $\alpha\alpha'\beta\gamma$ or $\alpha'\alpha\beta'\gamma'$ subunits indicating that two trimers are necessary to form the active sites. Structures, complexed with either HS-CoM plus HS-CoB or CoM-S-S-CoB, have been the basis for a proposed reaction mechanism. The relative positions of CoM, CoB, and F_{430} in the crystal structure suggests a nucleophilic attack of [F_{430}]Ni(I) on CH_3-S-CoM which forms the [F_{430}]Ni(III)-CH_3 intermediate. In the next step, [F_{430}]Ni(III) oxidizes HS-CoM producing the thiyl radical •S-CoM and [F_{430}]Ni(II)-CH_3. In the final step, protonolysis of [F_{430}]Ni(II)-CH_3 releases methane and the thiyl radical is coupled to $^{-}$S-CoB to form the heterodisulfide (CoB-S-S-CoM) accompanied by a one-electron reduction of Ni(II) to the active redox state. The binding of CoM induces specific conformational changes that ensures entry of CH_3-S-CoM adjacent to F_{430} and before entry of CoB in the narrow active-site channel.

Heterodisulfide reductase catalyzes the final step in Fig. 3 releasing the active sulfhydryl forms of the cofactors. The enzyme is comprised of two subunits (HdrDE). The smaller HdrE is a *b*-type cytochrome containing low-spin and high-spin hemes. HdrE accepts electrons from methanophenazine, a component of the membrane-bound electron transport chain. HdrE donates electrons to HdrD, which contains two Fe_4-S_4 centers, one of which is the proposed active site together with a redox-active disulfide of two cysteines. On the other hand, it has been proposed from kinetic experiments with the heterodisulfide reductase from *Methanosarcina thermophila* that the low-potential heme is involved in reduction of the heterodisulfide. In both pathways, heterodisulfide reduction is coupled to formation of an electrochemical proton gradient that drives ATP synthesis catalyzed by an A_1A_0-type ATP synthase. It is hypothesized that a proton gradient is generated across the membrane in a mechanism in which the protons are translocated upon electron transfer from methanophenazine to the heterodisulfide.

2.2 Reactions Involved in the Synthesis of CH_3-H_4 MPT

2.2.1 Carbon Dioxide Reduction Pathway

In most methanogenic environments, the six electrons needed for carbon dioxide reduction to CH_3-H_4MPT derive from the oxidation of either hydrogen gas or formate as shown in reactions (3–5).

$$H_2 + 2\ \text{ferredoxin}^{ox} \longrightarrow 2\ \text{ferredoxin}^{red} + 2H^+ \quad (3)$$

$$2H_2 + 2F_{420} \longrightarrow 2F_{420}H_2 \quad (4)$$

$$2HCOOH + 2F_{420} \longrightarrow 2F_{420}H_2 + 2CO_2 \quad (5)$$

Reaction (3), catalyzed by the Ech hydrogenase, is endergonic given the low partial pressures of hydrogen gas in the native environment; however, it is proposed that the Ech hydrogenase utilizes the electrochemical proton gradient to drive the reaction. Coenzyme F_{420}-dependent hydrogenases (reaction 4) and a formate dehydrogenase (reaction 5) have been characterized. Coenzyme F_{420} is an obligate two-electron carrier involving hydride transfer. Six reactions are required for reduction of carbon dioxide to CH_3-H_4MPT (reactions 6–10).

$$CO_2 + MF + 2\ \text{ferredoxin}^{red} + 2H^+ \longrightarrow 2\ \text{ferredoxin}^{ox} + \text{formyl-MF} + H_2O \quad (6)$$

$$\text{formyl-MF} + H_4\text{MPT} \longrightarrow \text{5-formyl-}H_4\text{MPT} + MF \quad (7)$$

$$\text{5-formyl-}H_4\text{MPT} + H^+ \longrightarrow \text{5,10-methenyl-}H_4\text{MPT}^+ + H_2O \quad (8)$$

$$\text{5,10-methenyl-}H_4\text{MPT}^+ + F_{420}H_2 \longrightarrow \text{5,10-methylene-}H_4\text{MPT} + F_{420} + H^+ \quad (9a)$$

$$\text{5,10-methenyl-}H_4\text{MPT}^+ + H_2 \longrightarrow \text{5,10-methylene-}H_4\text{MPT} + H^+ \quad (9b)$$

$$\text{5,10-methylene-}H_4\text{MPT} + F_{420}H_2 \longrightarrow \text{5-methyl-}H_4\text{MPT} + F_{420} \quad (10)$$

In the first reaction (reaction 6), carbon dioxide is attached to methanofuran (MF) as the carbamate and reduced to the formyl level by formylmethanofuran dehydrogenase with ferredoxin as the electron donor. Reaction (7) is catalyzed by formylmethanofuran:tetrahydromethanopterin formyltransferase. Reaction (8) is catalyzed by N^5,N^{10}-methenyltetrahydromethanopterin cyclohydrolase comprised of two identical subunits with no prosthetic groups. Two mechanistically distinct N^5,N^{10}-methylenetetrahydromethanopterin dehydrogenases catalyze reaction (9), one that oxidizes reduced coenzyme F_{420} (reaction 9a) and the other that oxidizes H_2 (reaction 9b). The F_{420}-dependent enzyme is composed of one type of subunit, either as a hexamer or octamer, with no detectable prosthetic group. The other dehydrogenase is essentially a hydrogenase that contains no metals in contrast to all known mechanisms for hydrogenases. The enzyme catalyses the stereospecific transfer of a hydride ion from hydrogen gas into the *pro-R* position of the methylene carbon involving a pentacoordinated carbonium ion (CH_3^+=H_4MPT) transition state intermediate in which the *pro-R* hydrogen bond is protonated and exchanges with water. N^5,N^{10}-Methylenetetrahydromethanopterin reductase catalyses reaction (10). The enzyme is F_{420}-dependent, contains one subunit with no discernible prosthetic groups, and exhibits a ternary complex kinetic mechanism suggesting direct hydride transfer.

2.2.2 Acetate Fermentation Pathway

Most of the methane produced in nature derives from the methyl group of acetate (reaction 1). In *M. thermophila*, CH_3-H_4MPT is synthesized by reactions (11–13).

$$CH_3COO^- + ATP \longrightarrow CH_3CO_2PO_3^{-2} + ADP \quad (11)$$

$$CH_3CO_2PO_3^{-2} + \text{HS-CoA} \longrightarrow CH_3COSCoA + Pi \quad (12)$$

$$CH_3COSCoA + H_4SPT + H_2O + \text{ferredoxin}^{ox} \longrightarrow CH_3 - H_4SPT + \text{ferredoxin}^{red} + CO_2 + \text{HS-CoA} \quad (13)$$

Acetate kinase (reaction 11) and phosphotransacetylase (reaction 12) function together to convert acetate to acetyl-CoA. The crystal structure of acetate kinase from *M. thermophila* reveals an α_2 homodimer with overall features suggesting that the enzyme belongs to the Sugar Kinase/Hsc70/Actin superfamily of phosphotransferases and is possibly the original member of this superfamily. Kinetic and biochemical analyses of site-specific replacement variants indicates a direct in-line mechanism in which the transition state phosphate is stabilized by Arg91 and Arg241. The CO dehydrogenase/acetyl-CoA synthase (Cdh) five-subunit complex cleaves the C−C and C−S bonds in the acetyl moiety of acetyl-CoA, transfers the methyl group to H_4SPT, and oxidizes the carbonyl group to CO_2 (reaction 13). The complex is divisible into three enzyme components. The nickel/iron-sulfur (Ni/Fe-S) component contains the CdhA and CdhB subunits. The corrinoid/iron-sulfur (Co/Fe-S) component contains the CdhD and CdhE subunits. The CdhC subunit constitutes the third component. Three metal clusters (A, B, and C) contained in the complex have properties nearly identical to three metal clusters in the well-characterized clostridial synthase for which functions have been assigned. Thus, cluster A is the proposed site for cleavage of the C−C and/or C−S bonds of acetyl-CoA, whereas the carbonyl group is thought to be oxidized on cluster C. Cluster B is a conventional Fe_4-S_4 center proposed to shuttle electrons from cluster C to the ferredoxin. Dissociation of CdhC from the complex results in loss of an EPR signal diagnostic of cluster A; a result identifying the location of cluster A in CdhC. Finally, the methyl group is transferred to the corrinoid cofactor III of the Co/Fe-S component in which H_4SPT is methylated.

3 Molecular Biology

Over the last decade, two significant advances in molecular biology have greatly facilitated our progress towards a more complete understanding of the biochemistry and physiology of methanoarchaea. First, the sequencing of complete methanoarchaeal genomes has revolutionized approaches to cloning methanoarchaeal genes and characterizing the functions of unknown genes. Second, the development of improved genetics tools has enhanced the ability of researchers to investigate methanogenic processes using genetics approaches. A third exciting discovery in methanoarchaeal genetics has been the expansion of the genetic code to include pyrrolysine, the twenty-second genetically encoded amino acid. This section of the review will briefly summarize the general features of methanoarchaeal genetics and then focus on recent advances in the molecular biology of the methanoarchaea.

3.1 General Features

Methanoarchaea and other Archaea share some genetic features in common with

both Bacteria and Eucarya. Like Bacteria, Archaea lack a membrane-enclosed nucleus and have a relatively small genome (1.66 to 5.75 Mbp) with circular chromosomal DNA and extrachromosomal elements. Some methanoarchaea, particularly members of the family Methanosarcinaceae, possess operons as well as bacterial-like regulatory mechanisms for gene expression. Furthermore, messenger RNA molecules contain a ribosome-binding site that is similar to the Shine–Dalgarno sequence of Bacteria. However, although Archaeal and Bacterial ribosomes are similar in size (70 S), rooted trees comparing small subunit rRNA sequences indicate that Archaea and Eucarya may share a common lineage separate from that of Bacteria. As predicted from this relationship, some components of archaeal replication, transcription, and translation are more similar to those of Eucarya. For example, Archaea possess homologs of eucaryal histones as well as a single complex RNA polymerase that resembles eucaryotic RNA polymerase II in subunit composition. Archaeal transcripts tend to lack introns, but the promoters of methanoarchaea and other Archaea contain a Box A sequence that is similar to the TATA box of Eucarya. Homologs of the eucaryal transcription factors TFIIB, the TATA-binding protein, and TFIIS have been identified in Archaeal genomes. In both Archaea and Eucarya, translation is initiated using methionine rather than formyl-methionine, which is common in Bacteria.

Histone-like proteins purified from *Methanothermus fervidus* (Hmf) have been characterized, and these proteins share amino acid sequence similarity with a protein family that includes eucaryotic histone proteins (H2A, H2B, H3, and H4). X-ray crystallography of the recombinant forms of two methanoarchaeal histone homologs (HmfA and HmfB) shows that the three-dimensional structure of both proteins resembles the characteristic histone fold of eucaryal core histone proteins. HmfA and HmfB may form homodimers, heterodimers, and tetramers in solution, but have not been observed to associate into octamers, which are typical of eukaryotic nucleosomes. The crystal structure of the histone-like protein from *Methanopyrus kandleri* (Hmk) has also been determined. Hmk is twice as long as HmfA, HmfB, and eucaryal histones, and contains two histone folds per monomer. The precise function of methanoarchaeal histone-like proteins has not yet been determined, but tetramers of Hmf interact with DNA and may play roles in regulation of gene expression or protection of DNA against heat denaturation.

3.2 Transcription

Gene expression in Archaea is said to resemble Bacteria in form and Eucarya in function. Similarities between Archaea and Bacteria include circular chromosomal DNA, the occurrence of transcription and translation in the same cellular compartment, the organization of some genes into operons, the absence of introns in protein-encoding genes, minimal post-transcriptional modification of mRNA, similarity in ribosome size, and the presence of a Shine–Dalgarno-like sequence to direct translation initiation. Interestingly, there are also a number of similarities between eucaryal and archaeal transcription and translation including the complexity of DNA-dependent RNA polymerases, promoters that contain TATA-box-like elements, transcription factors, elongation factors II that can be ribosylated with ADP,

introns in certain rRNA and tRNA genes, and translation beginning with methionine rather than formylated methionine.

3.2.1 RNA Polymerase

Bacteria contain a single DNA-dependent RNA polymerase composed of four different subunits with the stoichiometry of $\alpha_2\beta\beta'\sigma$. In contrast, Eucarya have three different nuclear RNA polymerases (I, II, and III), which function in rRNA synthesis (I), mRNA synthesis (II), and tRNA and small RNA synthesis (III). Each of the eucaryal RNA polymerases contains two large subunits and 8–12 smaller subunits. The large subunits A and B correspond to the β' and β subunits respectively of the bacterial RNA polymerase. Archaeal species possess a single DNA-dependent RNA polymerase, composed of about 12 subunits which may include B, A′, A″, D, E, F, G, H, I, K, L, and N. In some Euryarchaeota, subunit B appears to be divided into two fragments, B′ and B″, which respectively correspond to the C-terminal and N-terminal halves of subunit B. The deduced amino acid sequences of Archaeal A′ and A″ components have similarity to eucaryal subunit A and bacterial subunit β', while B (or B′ and B″) are similar to eucaryal B and bacterial β. Archaeal subunit H bears homology to a eucaryal subunit (RPB5) that is present in all three eucaryal RNA polymerases but has no counterpart in the bacterial holoenzyme.

3.2.2 Promoters and Terminators

The general features of methanoarchaeal promoters are illustrated in Fig. 4. A consensus sequence for the Archaeal promoter sequence called Box A has been determined from analysis of numerous rRNA, tRNA, and protein-encoding genes. Box A consists of a stretch of

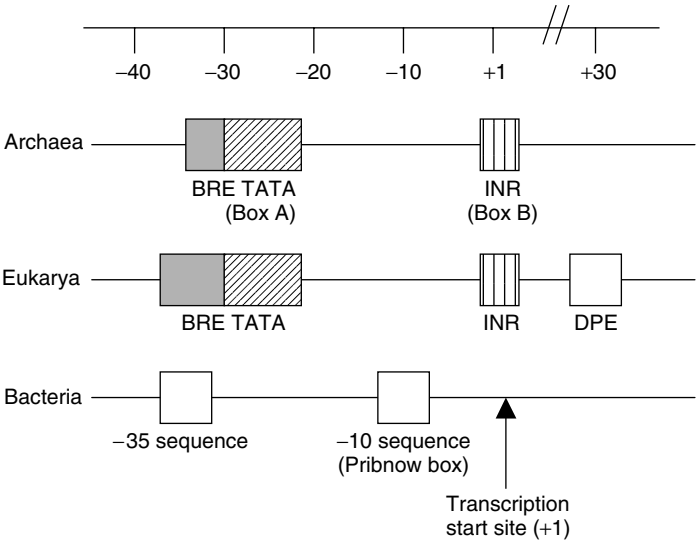

Fig. 4 Components of archaeal, eucaryal, and bacterial promoters. Archaeal and eucaryal promoters typically contain a TATA box sequence, a BRE, and an INR in the vicinity of the transcription start site. Eucarya may have a downstream promoter element (DPE). Bacterial promoters typically consist of a −35 and −10 consensus sequence.

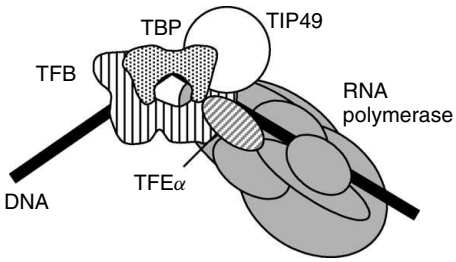

Fig. 5 Proposed model for the archaeal preinitiation complex. The TBP and TFB bind to DNA and recruit the complex archaeal RNA polymerase. Transcription activator factor TFE α is present in all sequenced archaeal genomes. A TBP-interacting protein homolog (TIP49) is also found in the genomes of *M. kandleri* and several hyperthermophilic sulfur-dependent archaea. Adapted from.

six nucleotides TTTA (T/A) A with similarity to the eukaryotic TATA box and is centered approximately 27 nucleotides upstream of the transcription start site. When the Archaeal consensus promoter sequence is replaced with the eukaryotic TATA box, transcription efficiency decreases to 13% of its original activity. Most methanoarchaea genes contain a second consensus sequence called box B or the initiator element (INR), which is located around the transcription start site. In the methanoarchaea, the INR consensus sequence (ATGC) transcription begins at the G position. In addition, a pair of adenines positioned approximately 33 and 34 nucleotides upstream of the transcription start site functions as a recognition element for transcription factor B (TFB) and is called the BRE (B recognition element) sequence. In Eucarya, the role of the TFB homolog (TFIIB) is to cooperate with transcription factor TFIID to assist in the binding between the TATA box and RNA polymerase II. The subunit of TFIID that specifically interacts with the eukaryotic TATA box is called the *TATA-binding protein* (TBP), and a homolog of TBP functions in Archaea. An archaeal homolog of transcription factor TFIIE has been shown to stimulate transcription from *M. thermoautotrophicus* promoters in an *in vitro* system. A proposed model for the archaeal preinitiation complex is shown in Fig. 5.

Two different potential termination signals have been found in Archaea. The first is an oligo-T sequence or a T-rich stretch of polypyrimidines. The second consists of short inverted repeats that may form stem-loop structures to direct termination. In thermophiles, transcription termination appears to be relatively inefficient, usually occurring at different sites within polypyrimidine stretches 4–30 nucleotides long.

3.2.3 Messenger RNA

Archaea contain polycistronic transcriptional units that resemble bacterial operons. Unlike most bacterial operons, however, Archaeal transcriptional units may contain internal promoters and terminators. In some cases, transcripts of different lengths are produced from the same operon, consistent with mRNA processing. No introns have been found in Archaeal or bacterial mRNAs that encode proteins; however, some Archaeal rRNA and tRNA transcripts contain sequences that are subsequently removed by posttranscriptional modification. At present, there is no evidence for posttranscriptional modification of mRNA in Archaea. RNAs with short poly(A) tails (about 12 nucleotides in length) have been found in Archaea, but they have not been experimentally identified as mRNA. The 5′ cap structures found in eucaryal mRNAs are not found in

Archaeal mRNAs. Ribosome-binding sites complementary to the 3′ terminus of the 16S Archaeal rRNA and similar to bacterial Shine–Dalgarno sequences are present in methanoarchaea mRNAs.

3.3 Translation

Archaea use the same universal genetic code as Bacteria and Eucarya. Codon usage generally depends on the GC content of the organisms, which varies from 26 to 71% in Archaea; thus GC-rich Archaea tend to prefer codons with G or C in the third position, although exceptions have been observed. The most common translation initiation codon is AUG, but GUG and UUG are also used. The ribosomes and other translational machinery used in the different domains exhibit distinctive qualities unique to each of the three lineages. Eucaryal translation differs from bacterial translation in several ways. Translation in Eucarya is posttranscriptional; mRNAs generally encode only a single gene; mRNAs are modified with a 5′ cap (7-methylguanosine) and a polyadenylated tail; the ribosome recognizes the 5′ cap structure of mRNA rather than a Shine–Dalgarno sequence; translation is initiated with methionine rather than formylated methionine; and initiation requires up to 10 additional protein factors. Translation in Archaea has some bacterial and some eucaryal features. Since no nuclear membrane is present, Archaeal transcription necessarily occurs in the same compartment as translation; mRNAs may be polycistronic, and posttranscriptional modification of mRNAs is not observed. Shine–Dalgarno sequences are utilized in some Archaea, but are unnecessary in others. As in Eucarya, translation is initiated with nonformylated methionine and uses a diphtheria-sensitive elongation factor (EF-2).

3.3.1 Transfer RNA

The tRNAs of Archaea contain several modified nucleotides present in Bacteria and Eucarya (pseudouridine, 2′-*O*-methylcytidine, 1-methylguanosine, and N^2N^2-dimethylguanosine), but lack ribothymidine and 7-methylguanosine, which are present in Bacteria and Eucarya. Archaeal tRNAs contain additional modified nucleotides unique to the Archaeal domain. Several aspects of Archaeal tRNA synthetases differ from the model systems described in Bacteria, including different mechanisms for charging asparagine, cysteine, glutamine, and lysine tRNAs.

3.3.2 Initiation and Elongation Factors

The number of protein factors required for archaeal initiation is unknown; however, it has been proposed that Archaea may possess initiation factors similar to those in Eucarya because hypusine, an unusual amino acid previously found only in eukaryotic initiation factor 5A, has been found in a *Sulfolobus* protein with sequence similarity to eukaryotic initiation factor 5A. The recombinant *M. jannaschii* initiation factor 5A homolog has been crystallized and contains a conserved lysine at position 40 that may be converted into hypusine *in vivo*. Archaeal elongation factors EF-1α and EF-2 contain regions that are highly conserved among elongation factors from all three domains. These conserved amino acid stretches are involved in GTP binding and hydrolysis. Interestingly, as in the eucaryal EF-2, one of the histidines at the C-terminus of the Archaeal EF-2 is posttranslationally modified to form

diphthamide, which makes it susceptible to ADP-ribosylation by the diphtheria toxin. Phylogenetic trees based on comparisons of EF-2 homologs are consistent with the clustering of Archaeal sequences on a branch separate from branches leading to eucarya or Bacteria; however, phylogenies based on EF-1α sequences are less consistent.

3.3.3 Archaeal Ribosomes

Archaeal ribosomes bear superficial similarity to those of Bacteria. Both Archaeal and bacterial ribosomes have a sedimentation coefficient of 70S and are composed of two subunits with sedimentation coefficients of 50S and 30S respectively. Archaeal rRNAs (23S, 16S, and 5S) are similar in size to bacterial rRNAs, but differ substantially in sequence. In terms of overall structure, Archaeal ribosomes appear intermediate in shape between eucaryal and bacterial ribosomes. For example, the small ribosomal subunits of Eucarya possess several bulges and gaps, plus a "bill" that is not present in bacterial ribosomes (Fig. 6). All Archaeal ribosomes possess a bill in their 30S ribosomes; however, only ribosomes from sulfur-dependent hyperthermophiles possess the other eukaryotic features.

3.4 Complete Genome Sequences

Sequencing of the complete genomes of five representative methanoarchaea has led to genome-level comparisons among organisms of different species and domains and simplified strategies for determining the function of unknown methanoarchaea genes. The first Archaeal genome to be sequenced was that of the hyperthermophilic methanoarchaeon *Methanococcus jannaschii*. The genome consists of a 1.66-Mbp chromosome with 1682 predicted protein-encoding genes, a large circular extrachromosomal element, and a small circular extrachromosomal element. Initially, putative cellular functions could be assigned to only 38% of the predicted genes. Genome sequencing has confirmed the similarity of Archaeal and eucaryal proteins involved in the processes of replication, transcription, and translation. For example, the *M. jannaschii* genome contains homologs of eucaryal histones, RNA polymerase

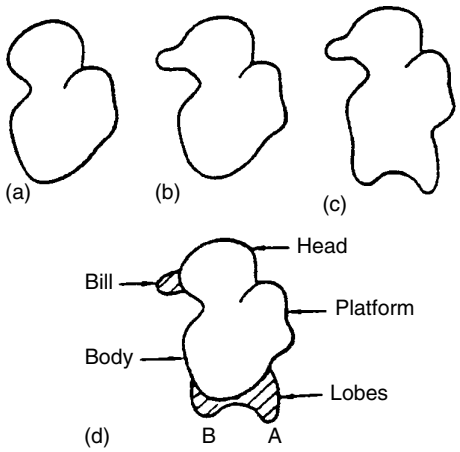

Fig. 6 Diagrammatic representation of small ribosomal subunits from (a), Bacteria, (b) Archaea, and (c) Eucarya. The striped regions (d) show the archaeal and eucaryal bill regions and the lobes (A and B). [From J. A. Lake, E. Henderson, M. W. Clark, and A. T. Matheson, *Proc. Natl. Acad. Sci. U.S.A.* **79**: 5948–5952 (1982).]

subunits, transcription-initiation factors, selected ribosomal subunits, and some aminoacyl–tRNA synthetases. However, homologs of the aminoacyl–tRNA synthetases for glutamine, asparagine, lysine, and cysteine are notably absent. The genome contains a tRNA for selenocysteine, which is encoded by the UGA stop codon, as well as four genes with internal UGA codons that are predicted to encode selenocysteine.

The genome sequence of *M. jannaschii* has provided an invaluable resource for cloning methanoarchaeal genes for expression in *Escherichia coli*. In many cases, the thermostable nature of recombinant *M. jannaschii* proteins provides a convenient means of protein purification by heating cell extracts to denature thermolabile *E. coli* proteins. Problems involving codon-usage bias have been overcome by expressing genes in *E. coli* strains that contain rare codon tRNAs. To a large extent, this strategy has obviated the need for growing large quantities of strictly anaerobic methanoarchaea for use in protein purification. The approach has been particularly successful for identifying the genes encoding low abundance proteins, such as enzymes involved in biosynthetic processes.

Sequencing the complete genome of *M. thermoautotrophicus* ΔH provided the first opportunity to make genomic comparisons of methanoarchaea with other Archaea, Bacteria, and Eucarya. Forty-six percent of the predicted proteins have been assigned putative functions based on homology to known enzymes, 28% have homology to genes of unknown function, and 27% lack significant homology to any known sequence. Substantial divergence of *M. thermoautotrophicus* from *M. jannaschii* has been postulated on the basis of a low degree of conservation in gene organization and the observation that less than 20% of the *M. thermoautotrophicus* proteins show greater than 50% identity with *M. jannaschii* proteins. Homologs of two-component regulatory systems and heat shock-70 response proteins are abundant in *M. thermoautotrophicus* but absent in *M. jannaschii*. As in *M. jannaschii*, tRNA synthetases for asparagine, glutamine, cysteine, and lysine are unrecognizable, but interestingly, the translation machinery for selenocysteine is lacking in *M. thermoautotrophicus*. The genome contains homologs of the eucaryal TATA-binding proteins, TFIIB and TFIIS.

Methanopyrus kandleri is a hyperthermophilic methanoarchaea that grows at temperatures up to 110 °C. Phylogenies based on rRNA sequencing have placed this methanoarchaeon in a deeply branching position separate from all other known methanoarchaea. Whole genome sequence comparisons have provided a different perspective on this evolutionary model. Although *M. kandleri* diverges from other methanoarchaea according to 16S rRNA phylogenies, it clusters with *M. jannaschii* and *M. thermoautotrophicus* when the genomes are compared on the basis of either conserved gene order and content or concatenated alignments of ribosomal proteins. In contrast to other methanoarchaea, the *M. kandleri* genome contains a high proportion of negatively charged amino acids that may assist in adapting proteins to the high intracellular salt concentrations of this organism. In addition, *M. kandleri* has relatively few putative regulatory and signaling proteins and less evidence for the lateral transfer of genes from Bacteria.

In contrast, the genomes of *Methanosarcina acetivorans* C2A and *Methanosarcina mazei* Go1 reflect the wide metabolic diversity of the *Methanosarcinaceae* family. The 5.75-Mbp genome of *M. acetivorans*

C2A is three times larger than the three previously sequenced methanoarchaea genomes and shows evidence of extensive lateral gene transfer. Similarly, in the 4.1-Mbp genome of *M. mazei* Go1 greater than 30% of the open-reading frames are more closely related to bacterial homologs than Archaeal homologs. In *M. acetivorans* C2A, predicted coding regions account for 74% of the genome, substantially lower than the gene densities of *M. jannaschii*, *M. thermoautotrophicus*, and *M. kandleri* that all exceed 90%. The genome contains multiple copies of numerous genes; including genes for methanogenesis related enzymes, putative corrinoid proteins, and methyltransferases, TATA-binding proteins, and homologs of bacterial regulator proteins such as sensory transduction histidine kinases. *M. acetivorans* contains both class I and class II lysyl–tRNA synthetases. One of these may be involved in translating a UAG amber codon into pyrrolysine.

3.5 Use of Methanoarchaeal Genomes to Identify Coenzyme Biosynthesis Genes

One field that has reaped tremendous benefit from the sequencing of methanoarchaeal genomes is functional genomics, including the identification of genes involved in the biosynthesis of specialized methanoarchaeal coenzymes. Progress has been made in the elucidation of the pathways of methanoarchaeal coenzyme biosynthesis. However, prior to genome sequencing progress in identifying the biosynthetic genes was limited, due in part to the low abundance of the enzymes and the lack of a genetics system.

Published genome sequences have opened up new strategies for identifying coenzyme biosynthesis genes. For example, the complete *Methanococcus jannaschii* genome sequence enabled use of a secondary structure analysis program to identify a proposed tetrahydromethanopterin (H_4MPT) biosynthesis gene encoding an enzyme that catalyzes a reaction similar in mechanism to that of dihydropteroate synthase. The secondary structure analysis program predicted that *M. jannaschii* gene *MJ0301* encodes a protein that would demonstrate secondary structure features similar those of dihydropteroate synthase. When *MJ0301* was expressed in *Escherichia coli*, the resulting protein catalyzed the predicted reaction of H_4MPT biosynthesis. *MJ0301* was the first H_4MPT biosynthesis gene to be identified.

A second effective strategy for identifying genes involved in coenzyme biosynthesis has been to propose a mechanism for the enzymatic reaction, and then search for genes that show homology to proteins that catalyze a similar reaction. For example, the formation of the α-keto acid (S)-sulfopyruvate during coenzyme M biosynthesis is proposed to occur by oxidation of (S)-sulfolactate. This mechanism resembles that of malate dehydrogenase, and the *M. jannaschii* genome contains only two genes annotated as malate dehydrogenase genes (*MJ1425* and *MJ0490*). Only the recombinant *MJ1425* gene product efficiently catalyzes the reaction of (S)-sulfolactate dehydrogenase, implicating a role for the gene *MJ1425* in coenzyme M biosynthesis. The *MJ1425* protein also catalyzes the reduction of α-ketoglutaric acid to (S)-hydroxyglutaric acid, a component of the coenzyme H_4MPT. Using mechanistic predictions, at least 16 genes involved in coenzyme, amino acid, or nucleotide biosynthesis have been assigned biochemical functions.

A third strategy to facilitate the assignment of coenzyme biosynthesis genes has been to take advantage of clustered genes in Bacteria that synthesize analogs of coenzymes. The methylotrophic bacterium *Methylobacterium extorquens* AM1 synthesizes an analog of H_4MPT and contains a cluster of genes that encode proteins involved in the H_4MPT-dependent oxidation of methanol. Some of these genes code for proteins with similarity to uncharacterized archaeal proteins and have been tested as candidates for H_4MPT biosynthesis genes. One of the key enzymes of H_4MPT biosynthesis is ribofuranosylaminobenzene 5′-phosphate synthase (RFAP), which catalyzes the first committed step of the pathway. The N-terminal sequence of purified RFAP synthase from the methanoarchaeon *M. thermophila* has been used to determine the corresponding gene in the genomes of *M. jannaschii* and *M. thermoautotrophicus*. Fortuitously, an RFAP synthase gene homolog also occurs among the clustered bacterial genes required for H_4MPT-dependent metabolism in *M. extorquens*. Expression in *E. coli* of the putative RFAP synthase genes from *M. thermoautotrophicus* (*MTH0830*) and *M. extorquens* (*orf4*) has produced enzymes with RFAP synthase activity.

The highly developed genetics system of *M. extorquens* has recently been used to identify seven additional genes of H_4MPT biosynthesis. Using an enzymatic assay to measure levels of H_4MPT coenzymes in *M. extorquens* cells, it has been shown that deletion mutants lacking the RFAP synthase gene are incapable of producing H_4MPT. Using this assay as a screen, seven additional genes implicated in H_4MPT biosynthesis have been found in *M. extorquens*. Six of these genes cluster together with *orf4* and encode Archaeal like proteins of unknown function. The seventh gene (*dmrA*) codes for an analog of bacterial dihydrofolate reductase that catalyzes the NADPH-dependent reduction of dihydromethanopterin to H_4MPT. These studies demonstrate how bacterial model systems can be combined with complete genome sequences to assist in determining the functions of uncharacterized genes.

3.6 Genetic Systems

Recent advances in the development of genetic systems have opened up the possibility of creating mutants to investigate the physiology, biochemistry, and regulation of gene expression in the methanoarchaea. Genetic tools for creating random and site-directed mutants, complementation strains, and gene reporters have been developed in combination with improved plating techniques, transformation procedures, and selectable markers. Model genetics systems have been developed for *Methanococcus maripaludis* and *Methanosarcina* species, and some of the genetics tools are effective in other methanoarchaea of the same genus.

3.6.1 Methanococcus

One of the challenges of developing a genetics system for methanoarchaea has been the lack of suitable antibiotics and antibiotics resistance markers. Because of fundamental differences between the ribosomal proteins of Bacteria and Archaea, typical bacterial antibiotics are often ineffective as inhibitors of methanoarchaeal protein synthesis. The first antibiotic to be used in a methanoarchaeal vector was puromycin, which inhibits the growth of *Methanococcus* and *Methanosarcina* species at concentrations less than 5 $\mu g\ mL^{-1}$.

Methanococcal integration vectors have been created using the puromycin acetyltransferase gene (*pac*) from *Streptomyces alboniger* under the control of the promoter and terminator for the methyl coenzyme M methylreductase gene. Vectors for transposon insertional mutagenesis are also available. Transformation procedures in *Methanococcus* species include polyethylene glycol treatment of *M. maripaludis* cells, which produces over 100 transformants per μg of plasmid, and transformation of *Methanococcus voltae* protoplasts by electroporation.

A shuttle vector (pDLT44) allowing plasmid replication in both *M. maripaludis* JJ and *E. coli* has been developed on the basis of the methanococcal plasmid pURB500. From pDLT44, an expression vector has been created by adding the strong methanococcal histone promoter and a ribosomal binding site. The sensitivity of *Methanococcus maripaludis* to neomycin at concentrations between 100 and 250 μg ml^{-1} and the use of neomycin resistance genes has expanded the range of methanococcal genetics tools and allowed for deletion of multiple genes in a single organism and complementation using expression vectors.

Studies on the regulation of gene expression in *M. maripaludis* have focused on processes involving nitrogen metabolism and formate utilization. Nitrogen fixation, the reduction of atmospheric nitrogen to ammonia, is highly regulated in methanoarchaea and has provided an excellent model system for identifying regulatory components in *M. maripaludis*. As in Bacteria, nitrogenase activity and the expression of nitrogen fixation (*nif*) genes in methanoarchaea decrease when fixed nitrogen is available as ammonia. Growth of *M. maripaludis* under nitrogen-fixing conditions requires molybdenum (but not vanadium) and is inhibited by tungsten. These data are consistent with phylogenetic evidence that the *M. maripaludis* nitrogenase is related to the class of bacterial nitrogenases that contain iron-molybdenum cofactor. Nitrogenase is encoded by the structural genes *nifH, nifD*, and *nifK*, and accessory genes are required for assembly of the enzyme into an active form. The order of the *nif* genes in methanoarchaea (*nifHDKENX*) is the same as the order found in Bacteria, with the interesting exception that two homologs of the regulatory gene *glnB* are inserted between the *nifH* and *nifD* genes. The *glnB* homologs also occur in the *nif* gene clusters of *Methanosarcina barkeri*. In Bacteria, the *glnB* gene product is involved in regulation of nitrogen metabolism and can be uridylylated at a conserved tyrosine residue in the T-loop.

In contrast to the bacterial *nif* genes, the eight *nif* genes of *M. maripaludis* form a single operon that can be transcribed as one large transcript (or up to ten smaller transcripts depending on the growth conditions). Transposon insertion mutagenesis indicates that all of the genes except *nifX* are essential for nitrogen fixation activity. The function of *nifX* in both Bacteria and Archaea is unknown, but a role in either cofactor biosynthesis or regulation has been proposed.

Transcription of the *nif* genes of *M. maripaludis* is repressed by ammonia. Two sets of palindromic sequences have been found between the *nifH* promoter and the transcriptional start site. Directed mutagenesis of the *nifH* promoter region fused to a *lacZ* reporter gene indicates that the first palindrome, but not the second, is involved in the regulation of *nif* gene transcription by ammonia. A similar palindrome (GGAA-N6-TTCC) is also found in the promoter region of several other genes

involved in nitrogen metabolism, including genes for glutamine synthetase (*glnA*), an ammonia-dependent NAD synthetase homolog, and an operon containing a putative ammonia transporter gene and a *glnB* homolog. Genes controlled by this operator may constitute a nitrogen metabolism regulon under the control of a single repressor protein. The Archaeal *nif* repressor protein is a negative regulatory element, in contrast to the bacterial regulatory proteins NifA and NtrC, which are positive regulators (activators) of *nif* expression. When alanine is the sole nitrogen source, alanine represses transcription of both the *nif* operon and the *glnA* gene to an intermediate level. Both the first and the second set of palindromic sequences in the *nifH* promoter region are needed for alanine repression of *nif* gene expression.

The availability of ammonia and alanine also regulates the transcription of *glnA*. The *glnA* promoter has only one operator for binding the nitrogen repressor protein, but there appear to be three TATA boxes and three transcriptional start sites. The first promoter provides a low, constitutive level of *glnA* expression, while the other two promoters are regulated through an operator that resembles the first palindromic sequence of the *nifH* promoter.

Nitrogenases from both bacterial and archaeal sources demonstrate the phenomenon of ammonia switch-off, which is a posttranslational inactivation of nitrogenase in the presence of ammonia. In *Rhodospirillum rubrum*, ammonia addition leads to the reversible ADP-ribosylation of the *nifH* gene product. However, in *M. maripaludis* ammonia switch-off occurs without ADP-ribosylation. Deletion mutagenesis and genetic complementation studies show that the process requires the two novel *glnB* homologs found in the methanoarchaeal *nif* operon. Although bacterial GlnB homologs can be modified by uridylylation of a conserved tyrosine in the T-loop, the Archaeal homologs might not become uridylylated because the methanoarchaeal homologs lack the conserved T-loop.

The ability of *M. maripaludis* to grow on either formate or H_2/CO_2 provides a second system for studying gene regulation in methanoarchaea. The genome of *M. maripaludis* has two clusters of formate dehydrogenase genes. The neomycin and puromycin resistance genes have been used to construct individual deletion strains and double mutants lacking both of the *fdhA* genes. Both genes are required for maximal growth rate on formate, and deletion of both *fdhA* genes eliminates the ability to grow on formate. Promoter–*lacZ* fusions show that H_2 represses expression of formate operons, but formate concentration has no effect on expression.

3.6.2 Methanosarcina

The metabolic diversity of *Methanosarcina* species and the higher abundance of regulated genes and operons make this genus an attractive target for genetic analysis. Early technical obstacles to developing a genetics system for *Methanosarcina* species included the tendency of the cells to grow in clumps called *sarcina*, the low transformation efficiency, a paucity of selectable markers, and a lack of suitable vectors for mutagenesis and expression. Progress in establishing a facile genetics system began with the observation that *Methanosarcina* cells grow as single cells in a moderate salt (marine) medium, which enables the plating of single colonies. A second breakthrough in *Methanosarcina* transformation has been the use of liposomes to deliver DNA into protoplasts. This procedure increases the transformation efficiency of

M. acetivorans by up to five orders of magnitude over polyethylene glycol-mediated transformation and electroporation. Nine out of eleven *Methanosarcina* strains tested could be transformed using the liposome-mediated technology.

Shuttle vectors for use in *E. coli* and *Methanosarcina* species have been developed by modifying plasmid pC2A from *M. acetivorans* to contain a puromycin resistance gene, a multiple cloning site, and *lacZα* for blue–white screening. Because neomycin apparently does not inhibit *Methanosarcina* strains, pseudomonic acid has been used to develop a second selectable marker system. Pseudomonic acid is a structural analog of isoleucine and inhibits the charging of isoleucyl tRNA synthetases. The resistance gene codes for a pseudomonic acid–resistant isoleucyl tRNA synthetase created by mutagenesis of *ileS* from *M. barkeri*.

A plasmid that can be used for random *in vivo* transposon mutagenesis of *Methanosarcina* is now available. The suicide vector contains the *Himar1* transposase under the control of the methyl coenzyme M methylreductase promoter and mini-*Himar1* elements. Using transposons, a mutation conferring resistance to the methanogenesis inhibitor bromoethanesulfonic acid (BES) has been localized to a putative membrane transport protein that may be needed for BES uptake. Random transposon mutagenesis has also shown that the resistance of *M. acetivorans* to fluoroacetic acid involves the acetate kinase–phosphotransacetylase operon needed for growth on acetate.

Directed mutagenesis of proline biosynthesis genes in *M. acetivorans* has been accomplished by replacing wild-type genes (*proA*, *proB*, or *proC*) with the genes disrupted by insertion of puromycin or pseudomonic acid resistance genes. Liposomes containing the mutated linearized DNA are used to transform *M. acetivorans*, and replacement of the wild-type gene by homologous recombination produces proline auxotrophs. These mutants can be complemented with plasmids containing the wild-type genes.

This suite of genetic tools has been used to investigate the physiological role of the Ech hydrogenase (Ech) of *M. barkeri* Fusaro. Ech catalyzes the reversible reduction of ferredoxin by H_2, and its association with the cell membrane has led to a proposed role in (i) energy conservation, (ii) the endergonic reduction of CO_2 to CHO-methanofuran during hydrogenotrophic growth, or (iii) steps in the synthesis of acetyl-CoA and pyruvate for anabolism. A *M. barkeri* Fusaro mutant has been created in which a puromycin resistance gene cassette replaces the entire *echABCDEF* operon. As anticipated, cell extracts from the *ech* deletion mutant lack ferredoxin-dependent hydrogenase activity. The mutant grows normally on methanol, but is unable to grow on acetate, H_2/CO_2, or H_2/CO_2/methanol. The mutant produces methane from methanol, but not from acetate or H_2/CO_2. Bypassing the first step of methanogenesis from H_2/CO_2 by providing H_2 and formaldehyde results in methane production, suggesting that the mutant is defective in the first step of hydrogenotrophic methanogenesis. The mutant is also unable to convert CO and H_2O to CO_2 and H_2, indicating that the oxidative half-reaction of methanogenesis from acetate is also nonfunctional. The mutant can be complemented for all phenotypes by inserting a functional copy of the *echABCDEF* operon in a neutral chromosomal location. These data are consistent with a

role for Ech in the first step of methanogenesis from H_2/CO_2 and in methane production from acetate, which may both require a ferredoxin-dependent hydrogenase. An additional role for Ech in synthesizing pyruvate for anabolic pathways has been proposed because exogenous pyruvate restores the ability of the deletion mutant to grow on H_2/CO_2/methanol, consistent with a role for Ech in pyruvate biosynthesis. The experiments described demonstrate the usefulness of the improved genetic tools for functional genomics analysis and for genetics studies that address fundamental questions about methanoarchaeal physiology and biochemistry.

3.7 Pyrrolysine

An exciting recent discovery in methanoarchaeal genetics has been the expansion of the genetic code through characterization of pyrrolysine, the twenty-second genetically encoded amino acid. This molecule consists of a substituted pyrroline-5-carboxylate attached by an amide bond to the epsilon amino group of lysine (See Fig. 7). Like selenocysteine, pyrrolysine is encoded by read-through of a stop codon (in this case, UAG rather than UGA). The N-terminal sequence of the purified monomethylamine methyltransferase from *M. barkeri* MS corresponds to the gene *mtmB1*. Although the molecular mass of the purified protein (MtmB) is 50 kDa, the *mtmB1* gene contains an apparent in-frame UAG stop codon that would truncate the protein of at 23 kDa. Internal sequencing of MtmB and mass spectrometric analysis of peptide fragments suggest that lysine occurs at the position corresponding to the UAG codon. The x-ray crystal structures of the monomethylamine methyltransferase show electron density consistent with a lysine linked to a 4-substituted-pyrroline-5-carboxylate moiety at the UAG position. The substitution at the 4-position may be an amine or a hydroxyl group. On the basis of its position in the protein active site, the novel amino acid has been proposed to play a specific role in transferring methyl groups during catalysis.

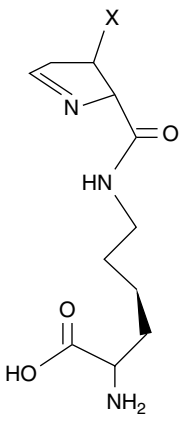

Fig. 7 Structure of pyrrolysine.

The mechanism of tRNA charging with pyrrolysine is currently being elucidated, and there is at present some controversy about the enzymes involved in the process. One investigation implicates the *pylTSBCD*L gene cluster located near one of the methyltransferase gene clusters of *M. barkeri* Fusaro. The *pylT* gene codes for a tRNA with a CUA anticodon capable of base pairing with the UAG codon. The protein encoded by *pylS* shares some homology with the core catalytic domains of class II aminoacyl–tRNA synthetases. Recombinant *M. barkeri* MS *pylS* expressed with an N-terminal six-histidine tag (His_6) in *E. coli* has been tested for lysine aminoacyl–tRNA synthetase activity. When combined with [^{14}C]lysine and

tRNA isolated from *M. barkeri*, His_6-PylS appears to catalyze the lysyl–tRNA synthetase reaction with an apparent K_m of 2.2 μM and an apparent k_{cat} of 1.6 min^{-1}. The K_m is comparable to the values found for other aminoacyl–tRNA synthetases. However, the k_{cat} value is between 12 and 5000 times lower than the rate obtained for other aminoacyl–tRNA synthetases. Given the low K_m for lysine, it is conceivable that the amber codon tRNA (PylT) is first charged with lysine and later modified to become pyrrolysyl-tRNA. A similar mechanism has been proposed for the biosynthesis of asparaginyl-tRNA, glutamyl-tRNA, and selenocysteinyl-tRNA. Because the proposed amber suppressor lysyl–tRNA synthetase (PylS) does not strongly resemble the typical class I or class II lysyl–tRNA synthetases, PylS is proposed to be a new class of lysyl–tRNA synthetase. In contrast, a second study presents contradictory evidence that His_6-PylS from *M. barkeri* Fusaro and *M. barkeri* MS cannot charge the amber suppressor tRNA (PylT) with lysine. Instead, it is proposed that PylT can be charged only if both the class I and class II lysyl–tRNA synthetases of *M. barkeri* are present in the reaction. Neither of the synthetases alone can catalyze the tRNA synthetase reaction. Further experiments will undoubtedly help resolve this inconsistency and provide further details on the genetic processes involved in incorporating pyrrolysine into proteins.

Keywords

Genomics
Analysis of gene expression of cell, tissue, or organ under given conditions.

Proteomics
Analysis of proteins of cell, tissue, or organ under given conditions.

Pharmacogenetics
Analysis of variability in drug responses attributed to hereditary factors in different populations.

Pharmacogenomics
Analysis of genome and its products (RNA and proteins) related to drug response.

Messenger RNA (mRNA)
The class of cellular RNA that undergoes extensive editing and that contains the protein-coding sequences of genes and functions as informational intermediate between DNA and protein.

Complementary DNA (cDNA)
The DNA version of the messenger RNA that is produced after a PCR reaction using reverse transcriptase (RT) enzyme (RT-PCR).

Gene Expression
The cellular process by which the genetic information flows from gene to messenger RNA, and finally to the protein.

DNA Microarrays
DNA (from bacterial clones or synthesized oligonucleotides) attached to a surface in an ordered, predetermined fashion at extremely high density; allow the monitoring of gene expression for thousands of genes simultaneously in a single hybridization experiment based on two principles of nucleic acid hybridization: (1) DNA and RNA (isolated from tissue specimens or cell lines) specifically interact with their complementary sequence attached on the array surface, and (2) this interaction happens in proportion to the amount of mRNA in the mixture.

Spotted DNA Arrays
Composed of cDNA clones arranged robotically on a nonporous surface (usually glass microscope slide or nylon membranes).

Oligonucleotide-based DNA Arrays
Composed of short (~25 bp) or long (~60–70 bp) oligodeoxynucleotides synthesized *in situ* directly onto a glass wafer, using a modification of semiconductor photolithography technology.

In April 2003, the 50th anniversary year of the discovery of the double-helical structure of DNA, a high-quality and comprehensive sequencing of the human genome was completely accomplished, and a revolution in molecular cell biology and molecular medicine had begun. Many complex questions arise (e.g. how genes contribute to normal human development, individual variability, and common diseases) and they need complex answers. It was necessary to develop techniques that permit complex answers. Microarray technology is a revolution technology that allows the simultaneous assessment of the transcription of tens of thousands of genes rapidly, as well as of their relative expression between normal and injured cells. There is widespread hope that microarrays will significantly impact on our ability to explore the genetic changes associated with etiology and development of many diseases, and to discover new biomarkers for disease diagnosis and prognosis prediction, and new therapeutic tools.

The present article provides an overview of microarray technology with accents on its recent advantages and limitations. The first chapter is focused on the basic principles of microarrays, array platforms and fabrication, and advantages and restrictions of cDNA-based (spotted) and oligonucleotide-based arrays (GeneChips and Codelink). The second chapter describes the crucial points in microarray study design (e.g. choice of reference source, sample preparation and preservation, labeling, and hybridization). Finally, a brief description of microarray data normalization, mining, and validation is given at the end of the review, transferring to several basic web sites and software with detailed explanation of this most underappreciated challenge facing researchers working on microarray projects.

1 Introduction in Functional Genomics and Proteomics

All mammalian cells have an identical copy of one and the same genome. However, the human organism consists of different types of cells, realizing different functions. The cell variety is a result of the expression (transcription) of different genes from the identical genome, and subsequent translation of their genetic information into different types and quantity of proteins. Therefore, the status of contemporary genetics might be succinctly summarized as follows: many genes, few functions.

Only 1 to 2% of the human genome codes expressed genes via messenger RNA (mRNA), which is translated into protein. The rest of the genome consists

of repeated sequences, regulatory regions, or unique noncoding sequences with unknown function.

The Human Genome Project (HGP) was begun in 1990, and its goal is the complete mapping and understanding of all the genes of human beings. Two groups, The International Human Genome Sequencing Consortium and Celera Genomics, simultaneously reported the draft sequencing of human genome in February 2001 (www.genome.gov). In April 2003, the 50th anniversary year of the discovery of the double-helical structure of DNA, a high-quality and comprehensive sequencing of the human genome was completely accomplished. HGP covers about 99% of the human genome's gene-containing regions with a sequence accuracy of 99.99%. The number of genes in the human genome was revealed to be approximately 30 000, which is considerably less than the initial estimation. At present, all of the initial objectives of the HGP have been achieved at least two years ahead of expectation, and a revolution in biological research has begun.

Each gene can be present in different variants, called *polymorphisms* (mostly single-nucleotide polymorphisms). To date, 3×10^6 gene polymorphisms are described – a number that increases daily and is estimated to be greater than 11×10^6 for the whole human genome. Each individual is composed of a pair of inherited combinations of variants for each of the 30 000 genes, explaining the enormous genetic diversity. Only a fraction of these gene polymorphisms is important to human health and disease, and to find the important ones and to predict the diseases is a major challenge for the next decades. The discovery of microarray technique (allowing relatively inexpensive study of all genes expressed in the genome/transcriptome in parallel) is a great promise in this field.

Before proceeding to the description of the principles and design of microarray studies, let us introduce the major definitions in molecular cell biology and molecular medicine as functional genomics, proteomics, pharmacogenetics, and pharmacogenomics (Table 1).

Not all of the genes in human genome are used simultaneously. Depending on the developmental stage, age of the individual, cell type, organ, and environmental factors, a different set of genes is transcribed into mRNA. The mRNA expression analysis under defined conditions is called *functional genomics*. It allows a comparison of different sets of genes used in different conditions – in norm and pathology. Most studies that apply microarrays are functional genomic studies.

Not all of the transcribed genes result in proteins. Moreover, practically all proteins are modified after the first assembly of amino acids. It has been established that a protein derived from the same gene can be

Tab. 1 Major definitions in molecular cell biology and molecular medicine.

Term	*Definition*
Genomics	Analysis of gene expression of cell, tissue, or organ under given conditions
Proteomics	Analysis of proteins of cell, tissue, or organ under given conditions
Pharmacogenetics	Analysis of variability in drug responses attributed to hereditary factors in different populations
Pharmacogenomics	Analysis of genome and its products (RNA and proteins) related to drug response

altered in 10 to 20 different splits and 3D forms. Some proteins interact directly with DNA, leading to gene silencing. Almost all of the proteins interact with other proteins within biochemical pathways and form protein networks. The analysis of the proteins of a cell, tissue, or organ under given conditions is called *proteomics*. Recently, techniques similar to microarrays have been introduced in proteomic studies.

There is a long gap from the genotype to phenotype. If the genotype would automatically lead to a specific condition, so-called phenotype, all identical twins would have exactly the same homeostasis and diseases. Although they considerably resemble each other, they also differ in many ways. Thus, a 100% match is not there between genotype and phenotype because of environment–gene interactions. On the other hand, many conditions are a result of pathogenic mechanisms, and despite the different genetic makeup of the individuals, the same phenotype arises, resulting in development of one and the same disease (for example, hypertension, asthma, diabetes, etc.). In these so-called complex diseases, a constellation of different susceptibility and disease-modifying genes need to be present. Research has therefore failed to identify specific disease genes, for example, an ''asthma gene,'' a ''hypertension gene,'' a ''diabetes genes,'' and so on. To understand the functional aspects of the disease better and to bridge the long gap between genotype and phenotype, it is necessary to combine functional genomic and proteomic analyses.

For complex questions (e.g. how genes contribute to normal human development, individual variability, and common diseases), there might be complex answers. Thus, it is necessary to apply techniques that permit complex answers. Therefore, novel techniques are necessary to screen thousands of genes more rapidly and to generate new hypotheses. This is the role of high-throughput technology, like microarrays. Although this technology is new, it has already resulted in significant research advances and its use is spreading rapidly. As a hypothesis-generating approach, high-throughput methods can lead to the identification of a set of potentially interesting genes associated with a certain condition, so-called candidate genes. Microarray techniques, however, will not replace the classical hypothesis-driven research. Identified candidate genes have to be validated for their function and relevance by classical approaches. It is necessary to have in mind that each method of investigation has its limits and must be interpreted properly. For example, although several genes in a particular metabolic pathway may show changes at the mRNA level, the actual function of that pathway may not be affected if none of these genes is a rate-limiting factor. Therefore, these high-throughput genome-level technologies must be interpreted within the appropriate biological context.

This review summarizes the current state of microarray technology and presents examples of its application for translation of genome from laboratory to clinic. All about microarrays can be found in www.arrayit.com.

2 Microarray Technique – Historical Background and Basic Principles

DNA microarrays had first been described by Patrick Brown's Lab in 1995. Since that original report, the number of microarray publications has increased exponentially, from less than 150 publications in the

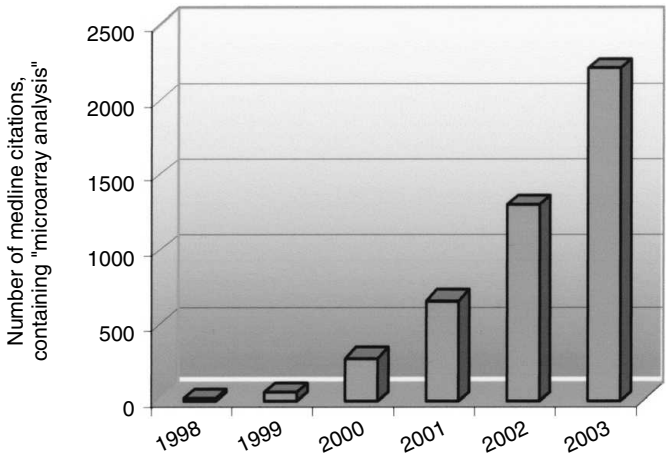

Fig. 1 Pubmed citations, containing ''microarray analysis.''

first 4 years (1995–1999) to about 2000 publications in 2003 (Fig. 1).

DNA microarrays – also called *gene chips* – consist of DNA attached to a surface in an ordered, predetermined fashion at extremely high density. More than 20 000 genes (almost a half of expressed human genes) can be arrayed on a surface with the size of a glass microscope slide. Microarrays allow the monitoring of gene expression for thousands of genes simultaneously in a single hybridization experiment because of two basic principles of nucleic acid hybridization: (1) DNA and RNA specifically interact with their complementary sequence attached on the array surface, and (2) this binding happens in proportion to the amount of mRNA (termed as *mRNA abundance*) in a mixture.

Although microarray technology has been originally designed for depositing DNA onto solid support for gene expression profiling (expression arrays), it has been extended to DNA copy number analysis (comparative genomic hybridization arrays), and, recently, a similar technology has been pioneered for protein and antibody spotting (Panorama Antibody Microarray Cell Signaling, www.sigma-aldrich.com).

Figure 2 provides an overview of a typical DNA microarray experiment from the selection of bacterial clones for manufacturing of the microarrays and nucleic acid extraction from tissue specimens or cell lines to *in silico* analysis, mining, and validation of the microarray data obtained. Optional steps, such as laser capture microdissection (LCM) and RNA amplification are also indicated.

The aim of the typical microarray experiment is to measure the amount of a given mRNA species (transcribed genes) of a tissue or cell type. For this purpose, the mRNA (isolated from the analyzed sample, e.g. drug-treated patients or cells – case sample, or untreated patients or cells – control sample) is usually transformed by reverse transcription into complementary DNA (cDNA), which is more stable. cDNA (or mRNA itself) from the sample is applied to the array surface and is further hybridized for several hours to the microarray. Each specific mRNA sequence (corresponding to the expressed gene) is able to bind only to a single complementary

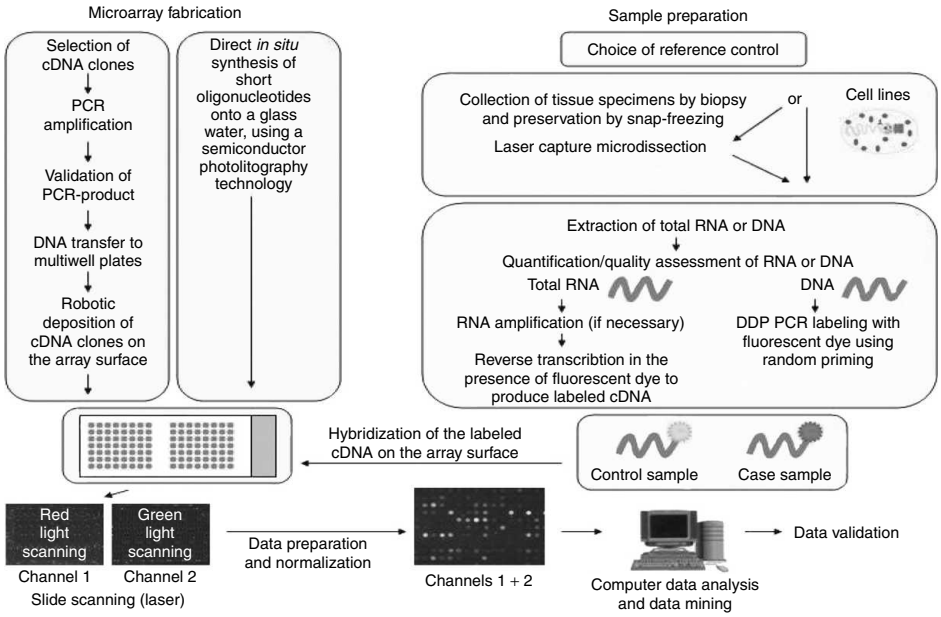

Fig. 2 Microarray study design.

oligonucleotide sequence attached on the array surface. If the mRNA sequence matches with the oligonucleotide sequence on a specific spot of the microarray, hybridization occurs. Direct information of how much of each gene is expressed in the cells is obtained by measurement of the amount of cDNA (corresponding to mRNA or expressed gene) bound to each spot on the array. The more abundant a given cDNA (or mRNA) is in a sample, the more it binds to its immobilized complement will occur on the array surface. The control and case samples are labeled with different fluorophores for detection. On each of the up to 450 000 spots, different binding intensities occur, depending on the concentration of the different cDNAs (equal to mRNAs or expressed genes) in the case and/or control samples tested. Thus, by comparison of the hybridization of cDNA from a control sample with that from a case sample, the relative amounts of all the genes present on the array and expressed in both samples can be measured.

In contrast to the conventional Northern blot, which analyses 1, 2, or up to 20 mRNAs, a microarray technique allows the simultaneous analysis of the expression levels of hundreds, thousands, or even tens of thousands of genes in a single experiment. The latest chips carry up to 450 000 spots for the analysis of more than 20 000 genes and gene sequences on a small glass slide (1.2 × 1.2 cm).

3 Array Platforms and Fabrication

Production of arrays begins with the selection of the probes to be printed on the array surface. These are often chosen directly from gene databases (e.g. GenBank, dbESt, and UniGene – all available on http://www.ncbi.nlm.nih.gov). Two main

methods are used to generate microarrays, and, currently, there are two main types of microarrays: cDNA arrays (also called *spotted arrays*) and oligonucleotide arrays (also called *GeneChips*).

3.1 cDNA-based (Spotted) Arrays – Advantages and Drawbacks

Spotted arrays had been originally developed in the Patrick Brown's Laboratory at Stanford University. They are composed of cDNA clones (selected from public databases and PCR-amplified) robotically arranged on a nonporous surface. A typical cDNA array is printed onto 30 × 15 mm glass microscope slide by a computer-controlled robotic cantilever arm; each spot is about 50 to 150 μm in diameter. cDNA clone sets of 15 000 to 20 000 mouse and 40 000 human genes are available for in-house arrays in addition to ready-made commercial chip sets. About 80% of all human genes are identified (the number increases daily) and can be queried on about two slides printed at high density. Other flexible and porous surfaces such as nylon membranes can be used as alternatives to glass. This approach allows the construction of arrays spotted with up to 80 000 spots.

The spotted arrays possess several advantages:

1. Affordability – they can be manufactured in-house.
2. Versatility – project-specific arrays (e.g. cancer arrays, immunoarrays, chromosome-specific arrays) can be custom designed.
3. Applicability to the simultaneous analysis of two different biological samples (e.g. treated vs untreated patient samples or cell lines, normal tissue vs malignant tissue, tumors of different stages vs a common internal reference), using two or more different fluorophores.
4. Finally, they provide the opportunity for discovery of novel genes since expressed sequence tags of unknown function can be spotted on the DNA arrays in addition to well-characterized genes.

The major restriction of spotted arrays is their inability to measure absolute levels of gene expression in biological samples, a measurement that GeneChips can provide. Several drawbacks are related to clone collections selected for spotting:

1. Clone collections must be sequence verified, a process that can be costly and time consuming.
2. Clone annotation needs to be updated regularly as new information becomes available in public databases.
3. Clones must be periodically reamplified by polymerase chain reaction (PCR), as the spotting process consumes DNA.

3.2 Oligonucleotide-based Arrays (GeneChips and Codelink) – Advantages and Drawbacks

Affymetrix Inc. (Santa Clara, CA, USA) owns a registered trademark – GeneChip®, which refers to its high-density oligonucleotide-based DNA arrays. However, in some articles appearing in professional journals, popular magazines, and on the WorldWideWeb, the term ''gene chip(s)'' has been applied, generally referring to microarray technology. Affymetrix GeneChips® are manufactured by synthesizing of *short oligonucleotides* (about 25 bp) *in situ* directly onto a glass surface, using a modification of semiconductor photolithography technology.

These arrays provide the advantage of an integrated platform, in which analytical tools are provided to the user in addition to the arrays themselves. The choice of microarray platform remains largely a user's personal preference, although it is often directed by budget considerations and local access and availability. These privileges are the reason for Affymetrix ChenChips® to be widely used in cancer research. The main restrictions of Affymetrix GeneChips® are in the impossibility to compare two biological samples directly on the same array and in their high cost that can be prohibitive to small research laboratories.

Agilent Technology (Palo Alto, CA, USA) offers arrays based on *longer oligonucleotides*. They are manufactured *in situ* by use of ink-jet printing technology. Many investigators use longer (60–70 bp) *oligonucleotide arrays* (e.g. Codelink arrays, Amersham Bioscience, Piscataway, NJ, USA) that are made in a way similar to cDNA arrays. However, these longer oligonucleotide arrays have an advantage that they do not require PCR-amplification and clone-insert purification before arraying. Several technical issues are recurrent challenges, as the optimization of slide surface and oligonucleotide attachment, and the design of the most specific oligonucleotide probe(s) for each gene. Cross-platform comparisons often yield significantly nonoverlapping results, and the source of these discrepancies is unknown.

Other techniques for measurement of gene expression that involve large-scale sequencing (such as serial analysis of gene expression – SAGE, and massively parallel signature sequencing – MPSS) can be more sensitive. These methods involve highly efficient identification of the expressed genes by sequencing of short fragments and counting of cDNA clones that correspond to mRNA expressed in a particular cell or tissue. However, neither technique is as rapid as a microarray, and, therefore, they are less likely to be useful in clinical practice.

This review will focus mainly on spotted (cDNA) microarrays. Excellent reviews of Affymetrix technology are available in Bibliography.

3.3 Fabrication of Spotted Arrays

The spotted microarrays are most commonly fabricated on poly-L-lysine-coated microscope slides (or surfaces of similar dimension). Other surface coatings that are also available include various silane derivatives, acrylamide gels, nitrocellulose, and nylon. Some of the microarray surfaces require the use of modified oligonucleotides or PCR-products for efficient attachment, while others rely solely on molecular charge to maintain binding of nucleic acid to the surface. The DNA fragments are cross-linked by UV to the matrix. After fixation, residual amines on the slide surface react with succinic anhydride to reduce the positive charge at the surface.

Several commercial robotic machines are currently used for fabrication of spotted arrays, for example, MicroGrid (BioRobotics, Cambridge, UK), GMS-417 (Genetic Microsystems, Woburn, MA, USA), OmniGrid (GeneMachines, San Carlos, CA, USA), and PixSys PA series (Cartesian Technologies, Irvine, CA, USA).

Several techniques are applied to replace DNA probe on the slide surface: Pin-to-Pin, Pin-and-Ring, Quill or Slit Pin, and Jetting (Piezo Electric, Inc Jet, Bubble Jet).

The *pin-to-pin technology* (Fig. 3) has the longest history of use as a spotting tool. Briefly, a series of pins is aligned on a

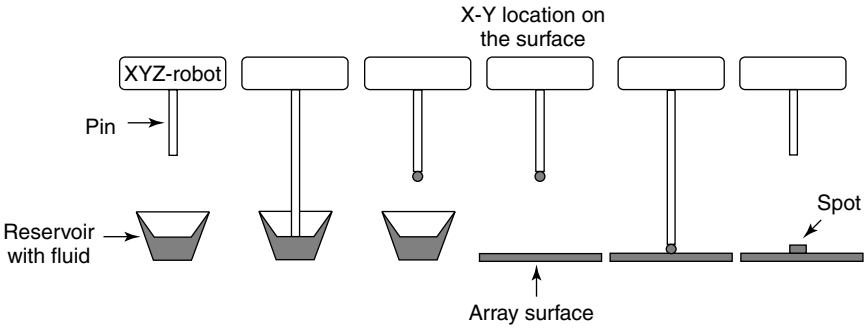

Fig. 3 Pin-to-pin technology.

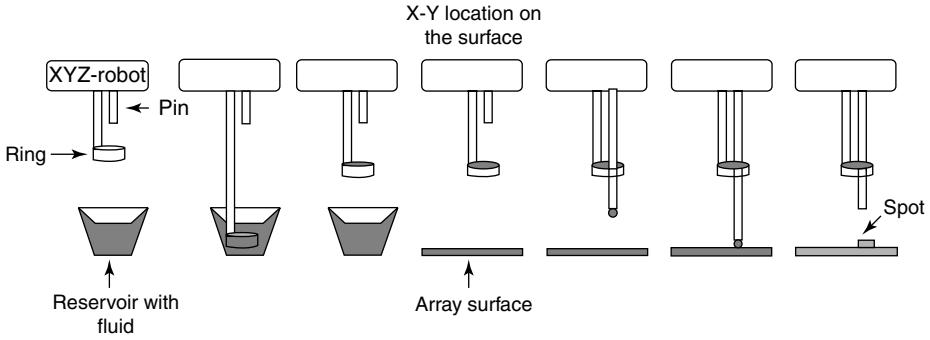

Fig. 4 Pin-and-ring technology.

head such that all the pins can be dipped into fluid reservoirs simultaneously (e.g. 96 pins, set in an array head, each pin at 9-mm center-to-center, for use with standard 96-well microplates). The pin-head module is attached to a 3D (x–y–z) robotic arm to move ''into'' and ''out'' of the wells, and to make contact with the spotting (array) surface. After dipping into the wells, the pins are lifted, and a small aliquot of fluid hangs on the tip of each pin by surface tension. These aliquots are transferred onto a slide surface through ensuring a pin–surface contact.

For fabrication of spotted microarrays on the microscopic slide surface, it is practically impossible to use more than 12 to 16 pins simultaneously, and the rate of the spotting is relatively slow. A crucial pint is the evaporation of the fluid aliquots during the time of transportation of the sample from the wells to the slide surface. This can provoke differences in the amount of fluid spotted and can introduce undesired variations into the arrays. Pin-to-pin alignment and consistency of pin dimensions are also both crucial points because of the necessity to place very small spots very close to each other, and to make at least a semiquantitative analysis of the hybridization to each spot.

The *pin-and-ring technology* (Fig. 4) has been specifically developed for fabrication of spotted DNA microarrays containing highly consistent elements. The key mechanical component consists of an open ring, which is oriented parallel to the wells (fluid reservoirs) and slide surface. The ring is fixed to a vertical rod, running perpendicular to the wells and slide surface.

A vertical pin is centered on the ring. Both the ring rod and the pin are attached to control devices so that each part can be moved separately in the z-axis. Both parts are kept in constant relation to each other in the $x-y$ plane. The spotting procedure includes several steps: the ring is dipped into the well (containing DNA solution) – the ring is small enough to fit easily into the well of either 96- or 384-well microplates; when the ring is lifted, it takes an aliquot of sample, which is held in the center of the ring by surface tension; the pin-ring device moves to any desired location in the $x-y$ plane and selects the place for spotting on the underlying surface; the pin is moved down through the ring; when the pin passes through the ring, a portion of the solution is transferred from the interior ring meniscus to the bottom of the pin – a pendant drop is formed on the pin tip; the pin continues to move down until the solution on the pin tip makes contact with the slide surface; the pin is then lifted; the combined forces of gravity and surface tension deposit the solution on the slide surface as a spot.

The pin-driving process can be repeated many times so that a very large number of similar spots can be created from a single moving ring. This consistency of spotting is the most important feature of the system. The spot size is dependent on pin dimensions and varies from 50 to 500 μm in diameter. It can be controlled by available hardware.

Special mechanisms have been designed to achieve a balance between the need to move the pin in z-axis rapidly, and to minimize the extent of contact between the pin and the slide surface. Thus, this technique is applicable for a wide variety of surface substrates – from solid glass to soft membranes and gels. The system appears to function well with a wide variety of fluids, ranging from volatile organic solvents to viscose aqueous solutions.

The *quills or slit pins* (Fig. 5) have been one of the most widely used devices for fabrication of spotted arrays. A quill is a solid pin with a slit at the end. The standard quill design looks very much like two tines of a fork, with a capillary between them. There are several variations of quills, but they all have the same principle of orientation. The quill is dipped into a fluid reservoir and the fluid is drawn up into the slit by capillary tension. The quill is moved to a desired position (in the $x-y$ plane) on the slide surface, then toward the slide surface (z-axis), and upon impact, the drop of fluid is placed on the surface. The quill

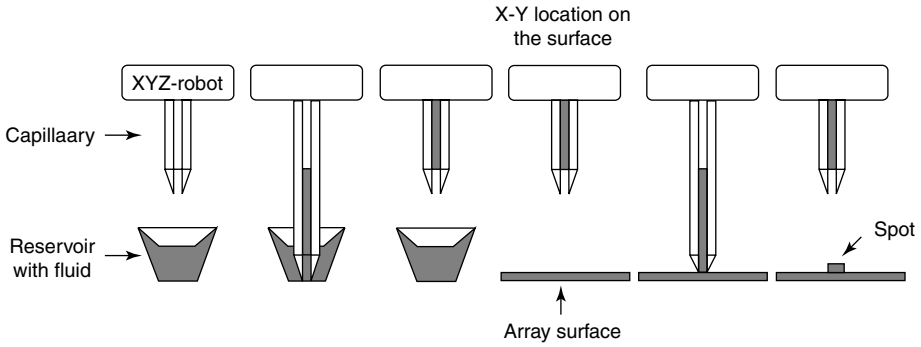

Fig. 5 Quill or slip pin technology.

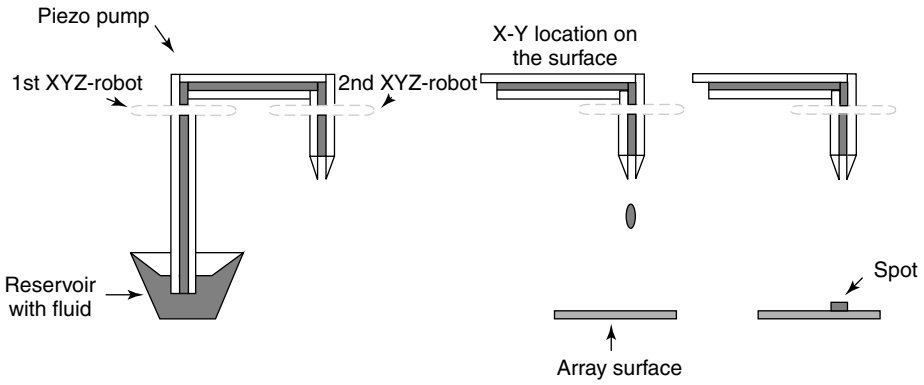

Fig. 6 Jetting technology.

is then withdrawn, moved to a subsequent location, and the process is repeated.

One of the advantages of the quill approach is that many quills can be attached to a single spotting head. One can spot 16 or more probes onto a surface simultaneously and without having to go back to the fluid reservoirs after each spotting. Therefore, this method enables rapid spotting. The quill has a relatively small void volume, and a little material is wasted. However, once the volume of the fluid in the quill becomes low, the amount of the spotted fluid begins to diminish with each subsequent spotting; this can compromise the quality of the arrays. The quill is also not highly effective for spotting of viscous solutions as a result of their difficult movement ''into'' and ''out of'' the capillary. The restriction of this technology is also due to the fact that it should be employed in a sterile environment because dust particles in the air or on the spotting surface can cause plugging of the quill. This characteristic of the quill limits its use to surfaces that are nonfibrous (as gels and membranes).

The *jetting technologies* (Fig. 6) had been originally developed for ink printing, and, nowadays, they are applied in microarray fabrication. They are based on syringes or piezo pumps.

The syringes offer a possibility of extremely fast jetting rates and exact repeatable volume deposition. However, the minimum volume they can dispense is about two orders of magnitude greater than other spotting techniques described above.

The piezo pumps are unidirectional pumps attached to flexible capillary tubing. The end of the tubing needs to be transferred from fluid to fluid by a 3D (x–y–z) robot. A second 3D (x–y–z) robot moves the other end of the tubing to a location above the surface onto which a drop of fluid has to be deposit. The pumps work with supply and wash solutions.

The piezo pumps offer a high speed and an ability to operate in any environment. However, there are several limitations: they cannot work with fluids containing long molecules, as well as with viscous fluids, because the glass heads easily become clogged; the spotting head is made of fragile glass that needs frequent repairs; this method of deposition often gives artifacts known as ''satellite'' spots that can compromise the quantitative analysis; a large volume of fluid is necessary to operate, and the void volume of fluid

is also high (100–500 μL). All these limitations make this technique less usable for microarray spotting.

4 Design of Microarray Experiment – Crucial Points

The most important factor for effective and successful microarray-based research projects is the careful experimental design, requiring a careful choice of the reference (control) source and unification of the experimental conditions. Even small variations in the conditions can induce significant changes in gene expression. For microarray analyses of human tissues, these variations include tissue-preservation methods, postmortem interval, dissection methods, and RNA quality. Frozen tissues usually provide the best material, although ethanol fixation can be also used. It is necessary to keep in mind that the differences in gene expression between samples may be due to differences in the genetic background (ethnicity). Other general sources of variability include cDNA amplification methods, probe labeling, hybridization conditions, and washing procedures. However, when these issues are taken into account in the experimental design and proper technique is applied, microarray experiments provide reliable data on gene expression.

4.1 Choice of Reference (Control) Source

One of the most critical decisions involves the choice of reference (control) sample when using dual-channel DNA arrays.

Several limitations have to be borne in mind during the design of a microarray-based project, especially in the clinic.

For example, for studies in cancer etiology and progression, the better choice is to compare a tumor (case) sample with a healthy (control) sample directly. It is ideal to obtain the healthy tissue from the same patient (case–control study). However, this possibility is often problematic and restricts the feasibility of this type of design. In this case, it is better to choose

Tab. 2 Labeling protocols for microarray experiments (according to Macgregor, P.F. (2003)).

Amount of total RNA	*Labeling mode*	*Protocols and kits*
>10 μg total RNA	Direct labeling (no amplification required)	Bittner, M. (2003) www.microarrays.ca
4–10 μg total RNA	Indirect labeling (no amplification required)	Randolph, J. et al. (1997) www.microarrays.ca
<10 μg total RNA	Amplification required before labeling:	
	-PCR-amplification	Vernon, S. et al. (2000) Livesey, F. et al. (2000) BD Atlas SMART Fluorescent Probe Amplification
	-Linear amplification	Eberwine, J. et al. (1992) Wang, E. et al. (2000) Arcturus RiboAmp Ambion MessageAmp aRNA

a comparison between tissue specimens obtained from the same patient before and after chemotherapy. This design is also limited by the impossibility to obtain sufficient amount of high-quality necrosis-free tumor tissue after chemotherapy. Because of these reasons, there is now a global trend to use a common internal reference in large microarray projects as the investigation of gene expression profiles of tumor specimens obtained from many different patients. This design increases the challenge to obtain global expression profiling across a large sample cohort, and it is already successfully applied by several groups. Commercially available reference RNA is often a good choice because of wide-gene-expression representation (e.g. Stratagene – La Jolla, CA, USA, and BD Bioscience Clontech – Palo Alto, CA, USA) and virtually unlimited availability. Finally, this approach allows easier comparison of microarray data between different research groups, thus providing the possibility of more global studies.

4.2 Labeling and Hybridization

Once the choice of reference source is made and the number of replicates decided, the actual labeling protocol depends predominantly on the amount of sample RNA (Table 2).

In studies using cell lines, RNA availability is usually not a problem. However, great care should be taken to ensure maximum reproducibility and stability in cell culture conditions, especially if RNA has to be isolated from cells during a long time interval.

In studies using human tumor tissues, RNA availability can be problematic because of the impossibility to obtain a sufficient amount of sample tissues every time.

Despite the amount of sample RNA, its high quality (degradation-free RNA) is crucial for successful microarray experiments. Assessment of RNA quality has been greatly facilitated by the use of microcapillary-based devices (e.g. Agilent Bioanalyzer, Agilent Technologies, Palo Alto, CA, USA), which can evaluate RNA quality and quantity using a little amount (~200 ng) of total RNA. More traditional techniques (such as agarose gel electrophoresis and spectroscopy) can also be used when RNA quantity is not limiting.

There are basically two labeling techniques, depending on the amount of RNA prepared for microarray analysis: direct and indirect labeling.

If the amount of total RNA available is in the range of 10 to 20 µg per experiment, direct labeling is the simplest choice. Direct labeling involves direct incorporation of Cy3- or Cy5-labeled dCTP during reverse transcription of RNA to cDNA. Usually 10 µg of total RNA are sufficient to obtain high-quality microarray signals using direct labeling.

If the amount of total RNA is slightly lower (in the range of 4–10 µg per experiment), indirect labeling can be used. In this case, the labeling proceeds in two steps: (1) a modified nonfluorescent nucleotide (e.g. amino-allyl dUTP) is incorporated into cDNA during the reverse transcription step, and (2) subsequent coupling to fluorophores is performed in a separate reaction.

Detailed protocols for direct and indirect labeling can be found in www.microarrays.ca.

If the amount of the sample RNA is only submicrograms (e.g. from limiting clinical samples, such as fine needle biopsies or LCM specimens), RNA amplification is

required before to proceed to the labeling. This strategy now enables the molecular profiling of biological samples down to few cells. Two amplification approaches have been used and commercial kits are available: PCR-based amplification (e.g. from BD Bioscience Clontech) and linear amplification (e.g. from Arcturus, Mountain View, CA, USA). In the case of necessity of RNA amplification, microarray results need more extensive validation. Moreover, the use of RNA amplification significantly increases the overall time and cost of molecular profiling of the samples.

After fluorophore incorporation, the fluorescent cDNA sample (probe) is hybridized to the microarray (target) at a temperature determined by the hybridization buffer used, in the presence of nonspecific competitors (e.g. yeast tRNA and salmon sperm DNA). The microarray is then washed under stringent conditions to remove nonspecific binding and is air-dried. The dried array is then scanned using a confocal laser scanner and the images obtained are quantified using image acquisition software.

The labeling and hybridization procedures, described above, are typical for the expression arrays.

A protocol very similar to the one used for expression arrays can be used for comparative genomic hybridization (CGH) arrays. In CGH arrays, the genetic material hybridized to the array is not RNA but genomic DNA, and the purpose is to investigate changes in gene copy numbers in tumor samples. Genomic DNA is extracted from tumor samples or normal tissue, digested with a restriction enzyme, such as EcoR1, and fluorescently labeled with Cy3 or Cy5 using random priming. Labeled DNAs are cohybridized to the microarray in the presence of blocking agent, usually Cot-1 DNA, yeast tRNA, and poly(dA-dT). After hybridization and stringent washes, the arrays are scanned and quantified in a process essentially identical to that described for expression arrays. CGH array experiments can be carried out using the same spotted arrays applied for expression analysis, thus providing the opportunity of a direct comparison on the same genes between gene copy numbers and expression levels. Alternatively, BAC arrays can be used, either manufactured in-house or commercially available, for example, from Spectral Genomics (Houston, TX, USA).

5
Data Analysis, Validation, and Interpretation

Perhaps the most underappreciated challenge facing researchers working on microarray projects is the extremely large quantity of data generated by this technology and the choice of an appropriate and effective database and data analysis system. In the early days of microarray technology, the basic data analysis was carried out using standard spread-sheet software, such as Microsoft Excell, or programs developed in-house. At present, there are a number of companies offering software for microarray data analysis. This is either offered free of charge on the Internet by academic institutions or it is commercially available (Table 3).

5.1
Normalization of Microarray Data

The first step in microarray data processing and analysis is the normalization. Normalization is used to combine the data from multiple microarray experiments into a single data set

for analysis. It is absolutely necessary to account for and to minimize the artifacts and experimental variations in the calculation of gene expression ratios. The normalization is a complex and often controversial issue in microarray data analysis, and a discussion of the different strategies is beyond the scope of this review. Briefly, there are two main approaches to normalization: (1) *intensity-dependent normalization*, in which a normalization factor is calculated on the basis of all spots on the array, and (2) *intensity-independent normalization*, which uses normalization function to equalize both channels (as Locally Weighted Scatter Plot Smoother, LOWESS – http://stat-www.berkeley.edu/users/terry/zarry/Html/). The results obtained after normalization are generally displayed as normalized expression ratios, where each row represents one spot on the array and each column represents one hybridization experiment. If some genes are represented by several spots on the array, it is possible to combine and average the expression ratios obtained for these different spots.

5.2 Statistical Data Analysis

In traditional data analysis, there are few variables and great number of replicates for each data-point. In microarray data analysis, there are many variables and a small number of replicates for each data-point. Microarray data analysis is typically carried out by one of two approaches – supervised or unsupervised (or a combination of both).

In the *unsupervised statistical analysis*, the data are analyzed without *a priori* assumption about the identity, characteristics, or clinical attributes of the specimens analyzed. Typical examples of unsupervised analysis in microarray data are 2D hierarchical clustering (software is now available – http://rana.lbl.gov), K-means clustering, self-organization maps (SOM), and binary tree–structured vector quantization (BTSVQ). Unsupervised clustering of microarray data is widely used in tumor classification, for instance, in leukemia, lung cancer, ovarian cancer, colon cancer, prostate cancer, or breast cancer.

The *supervised statistical analysis* of microarray data integrates some of the biological and clinical attributes available for the specimens analyzed. Typical examples of supervised analysis are significance analysis of microarrays (SAM) and prediction analysis of microarrays (PAM). Supervised data analysis is widely used for identification of genes capable of stratifying tumor samples based on one particular attribute, such as clinical outcome or response to treatment.

Detailed explanation of microarray data normalization and statistical analysis can be found in several books and reviews cited in Bibliography.

5.3 Microarray Data Validation

Microarray data analysis is a multistep process that uses sophisticated statistical analysis tools and is prone to errors and sometimes to overinterpretations. In addition, quality issue in the raw microarray data, for example, high background or low reproducibility, as well as nonlinearity of microarray signal will significantly impact on the final results. Finally, with spotted arrays, misidentification of probes can also lead to errors. Validation of gene expression data by conventional techniques is

essential. Usually, the validation of microarray data is carried out first at the RNA level by Northern blot, semiquantitative PCR, real-time quantitative (RT)-PCR, or *in situ* hybridization (ISH) on tissue sections or high-density microarrays (TMA). The microarray data can be also validated on the protein level by immunoblot analysis. Owing to the nonquantitative nature of immunoblotting, validation by other methods is required. An excellent example of such an extensive validation is presented in the study of Beer and colleagues, where the authors validated their microarray results both at the RNA level by Northern blot and at the protein level by IHC on tissue microarrays.

The development of high-throughput screening and validation technologies is an important priority because the number of genes identified through microarray studies rises exponentially.

5.4 Data Mining and Interpretation

Once gene data sets are identified and validated, data mining and interpretation is the ultimate challenge in microarray studies. It is not a trivial task to determine which of the hundreds of potentially differentially expressed genes identified are biologically relevant to the problem being investigated. Several bioinformatics tools and public databases provide information on the biological function, cellular localization, and gene ontology of the selected gene of interest: GenBank (www.ncbi.nlm.nih.gov), UniGene (http://ncbi.nlm.nih.gov/UniGene), PubMed (www.pubmed.com), US National Center for Biotechnology Information (NCBI) Databases (www.ncbi.nlm.nih.gov), Stanford Online Universal Resource for Clones and ESTs (SOURCE) (http://source.stanford.edu), SWISS SPOT (http://ca.expasy.org/sprot/). Another computer application of interest is GenMAPP, available online at www.genmapp.org. GenMAPP allows a visualization of gene expression data such as fold changes in expression ratios on maps representing biological pathways. Similarly, OntoExpress (www.openchannelfoundation.org/projects/Onto-Express/) correlates the identified genes with their functional and biological characteristics. Finally, literature searches can be greatly facilitated by using Internet text-mining tools, such as MedMiner, available at http://discover.nci.nih.gov/textmining/filters.html.

However, it is important to keep in mind that the complexity of the cellular machinery is extraordinary, and it is impossible to provide a biological explanation for every one of the genes identified by microarray analysis only with one simple click on the computer mouse. In addition, incorrect gene annotation in databases is a significant problem. Even when the genes identified in microarray analysis are correctly annotated, fully identified, and have a known function, many of these genes will belong to several biological pathways involved both in normal cellular processes and pathogenesis. In this context, downstream functional analysis using classical molecular biology approaches will remain paramount for the thorough interpretation of microarray findings.

6 Major Technical Restrictions

In order to perform genome-wide expression profiling, it is necessary to have *genome-wide microarrays*. In the case of

mouse and human, such whole genome arrays are on the horizon, although not yet available. This situation is likely to be resolved in the next two to three years, given the maturity of the genome and EST-sequencing projects in the mouse and humans. Certainly, the number of genes that can be investigated using microarrays increases all the time. It is likely that improvements in deposition or synthesis of DNA probes will allow a suitable density to be achieved, avoiding the requirement of hybridizing multiple arrays in order to achieve full genome coverage. The advent of spotted oligonucleotide arrays and related technologies also opens up the possibility of exon-specific probes for the detection of tissue-specific (or cell-specific) splice variants.

Perhaps one of the basic restrictions in the use of microarrays is *the limiting amount of RNA* available from standard tissue or cell specimens. The embryonic dissections used in developmental biology are a good example. A whole 7.5-dpc mouse embryo yields ~0.5 μg of total RNA. Usually, the conventional microarray hybridization analysis requires 5 to 100 μg of total RNA. It is clear that specific embryonic tissues or organs, especially from early stages, will yield only a fraction of the required target RNA. Embryo-sorting techniques have been employed, but target amplification appears to be the most widely applicable solution. A number of amplification protocols have been described that allow the generation of sufficient target from small amounts of staring RNA. It is not clear which protocol offers the ''best'' solution of the problem of limiting RNA because different scientists have different criteria for the assessment, including simplicity, reliability, and cost.

The last category of potential technical limitations of microarray analysis is closely related to *the possibility for identification of those incredibly rare transcripts* that encode those critical regulators of cellular homeostasis and development. A combination of variations in transcript abundance and cellular heterogeneity makes it difficult to perform expression profiling in standard tissue explants in a useful fashion. Subdissection and cell sorting are usually necessary; this makes labeling and hybridization practically impossible.

7 Application of Microarrays in Molecular Cell Biology and Molecular Medicine

What can be measured by microarrays?

Microarray technology can be used for three main applications:

1. Gene expression profiling – mRNA extracted from a biological sample is applied to the microarray. The result reveals the level of expression of tens of thousands of genes in the sample. This result is known as a gene expression ''profile'' or ''signature.''
2. Genotyping – DNA, extracted from a biological sample, is amplified by a PCR and applied to the microarray. The genotype for hundreds or thousands of genetic markers across the genome can be determined in a single experiment. This approach has considerable potential in disease risk assessment, both in research and clinical practice.
3. DNA sequencing – DNA extracted from a biological sample is amplified and applied to specific ''sequencing'' microarrays. Thousands of base pairs

of DNA can be screened on a single microarray for polymorphisms in specific genes whose sequence is already known. This greatly increases the scope for precise molecular diagnosis in single gene and genetically complex diseases.

In the medical practice, the precise diagnosis and effective treatment of disease depend on the ability of specialists to recognize the recurring constellations of clinical signs and symptoms that permit meaningful classification of the diseases. Unfortunately, the clinical signs and symptoms or even blood and pathological investigations are poor predictors of the clinical outcome or response to therapy. In the postgenomic era, studying of gene expression profiling will ultimately determine the biological behavior of both normal and injured tissues and cells, which may provide insights into disease mechanisms and help to identify novel candidates for therapeutic intervention. Gene profiling may also identify markers useful in diagnostic and prognostic purposes. Since thousands of genes are simultaneously and quantitatively analyzed on microarrays, this technology provides a resolution and precision not previously possible. Therefore, molecular phenotyping of diseases through gene expression profiling and sequencing may offer diagnostic, prognostic, and mechanistic insights that improve management of human diseases. Microarray technology has also a dramatic impact in the fundamental biological studies, providing an effective way to assess globally the transcriptional effects of specific genetic and pharmacological interventions, thus rapidly identifying possible up- and downstream effectors or alternative signaling pathways.

Keywords

Differentiation
A stable change in global patterns of gene expression usually producing a recognizably different type of cell.

Morphogenesis
The creation or development of an organism's or cell's morphology, structure, and form.

Development
A genetically programmed combination of differentiation and morphogenesis.

Cell Cycle
The orderly progression of events during cell proliferation through phases of growth, DNA replication, chromosome segregation, and cell division (cytokinesis).

Protein Kinase
An enzyme that phosphorylates itself and/or other proteins. Major categories of protein kinase are named according to the amino acid that is specifically phosphorylated, for example, tyrosine protein kinases phosphorylate target proteins on tyrosine residues.

Sigma Factor
A subunit of bacterial RNA polymerase that directs binding of the polymerase to specific DNA sequences (promoters), resulting in the transcription of downstream genes. Sigma factors form a family of polypeptides, each of which recognizes a different promoter sequence and so directs transcription of a different set of genes.

Transcription Factor
A DNA-binding protein that is not part of the RNA polymerase, but which binds to specific DNA sequences and regulates the expression of nearby genes by activating or inhibiting transcription.

Signal Transduction
The process whereby extracellular or intracellular, physical or chemical signals elicit a series of intracellular biochemical events in which each event either activates or inhibits the next.

Holdfast
A specialized attachment organ (of a multicellular organism) or organelle (of a unicellular organism).

Flagellum
A long, thin cellular appendage that is responsible for swimming motility – in the case of bacteria a rigid, helical, hollow filament that functions as a propellor attached to a rotary motor in the cell membrane through a semiflexible coupling.

Pilus
A long, fiberlike appendage on a bacterial cell that is thinner than a flagellum.

Pseudopod or Pseudopodium
A region of an amoeboid cell that does not contain membrane-bounded organelles and is extended outward during amoeboid movement.

Spore
A specialized, dormant, resistant cell formed as a means of dispersal from and survival of harsh conditions.

Endospore
A spore formed from a daughter cell within the membrane of a mother cell in certain bacterial species (notably of the genera *Bacillus* and *Clostridium*).

Sorus
A cluster or mass of spores.

Development is not only restricted to large multicellular animals and plants but is also a feature of the life cycles of microorganisms. The environment of a microorganism is rapidly changeable so that both eukaryotic and prokaryotic microbes have evolved developmental strategies to enhance their nutrient-scavenging abilities or in more extreme circumstances to form dormant, resistant cells (spores). The spores can survive under harsh conditions that do not support growth and can be dispersed to other environments that do. The endospores of pathogenic *Clostridium* species are amongst the most resistant cells on earth, and their destruction (or removal) is the key criterion for successful microbiological sterilization. Developmental programs in microbial pathogens are initiated in response to infection of the host and play important roles in pathogenesis. However, the best-understood examples of microbial development are not pathogens, but free-living microbes. The general principles underlying microbial development are being elucidated by their study.

1 Introduction

Biologists do not usually think of microbial model organisms when asking questions about the fundamental mechanisms of development. Yet, even in the most complex of metazoans, development involves cells doing things in an ordered way through space and time – growing, dividing, adhering to one another and to the substratum, differentiating, moving, secreting, and, above all, communicating – and the fundamental mechanisms of what cells do evolved very early in the history of life. So it should not be surprising to learn that the molecular mechanisms at the heart of these cellular processes in development are frequently similar.

At the same time, every organism in the tree of life has faced its own unique problems in using these primeval molecular mechanisms to meet the needs of its ''chosen'' life style. Each has accordingly evolved its own developmental programs using its own unique selection of molecular techniques to carry them out. So we are not surprised either that organisms belonging to different phylogenetic lineages have often opted for different molecular mechanisms to perform similar developmental functions or that in some lineages, particular molecular mechanisms have been elaborated upon, used, and reused in many different biological roles, while others are not used at all.

An example of these principles is to be found in the universal use of protein kinase cascades in signal transduction pathways controlling development. Yet there are differences. The histidine protein kinases are used in developmental signaling pathways in all of the major bacterial groups and in many eukaryotic lineages including the fungi, the slime moulds, and the plants, but not, it seems, in metazoan animals. No one knows why the use of histidine kinases was abandoned in the animal lineage, but retained in the next most closely related eukaryotic lineages. The bacteria, on the other hand, appear to make little, if any, use of the serine/threonine protein kinases so ubiquitously found in eukaryotic organisms. Differences like this tell us that there is nothing about one class of kinase compared to the other that makes its use essential for particular signaling purposes. They also identify classes of molecules that could be potentially used as targets for drug or antibiotic therapy. Histidine kinase signaling pathways participate in bacterial pathogenesis and are therefore potential antibiotic targets.

What then might be the general principles to be gleaned from our current understanding of development in eukaryotic and bacterial microbes? To attempt to answer this question I have opted in the following sections to discuss microbial development by describing what we know about developmental pathways in five well-studied systems – three bacterial and two eukaryotic. The emphasis is on the signaling cascades that control cellular activities in development. Having examined each of these five systems in some detail, I conclude by noting general features that seem to be shared by all.

2 Bacteria

2.1 Cell Cycle Control and Morphogenesis in *Caulobacter crescentus*

Bacteria are usually thought of as exhibiting one of only a limited number of cellular morphologies – rods, cocci, or

spirals – that is monotonously present in every cell. *Caulobacter crescentus* is different. An aquatic bacterium, common in freshwater environments characterized by low and patchy nutrient levels, *Caulobacter's* unique cell cycle involves polarized differentiation and cytofission to produce two morphologically distinct cells – a nondividing, motile, swarmer cell, and a sessile, stalked cell that is able to progress through cell division (Fig. 1). The swarmer cell is able to disperse by both random and chemotactic swimming motility to nutrient-rich microhabitats where it differentiates, losing its polar flagella and pili to replace them with a stalk and holdfast. Through these, it attaches to the substratum and begins progression through the cell cycle just as the mother cell did from which it was derived. It is this cell cycle, with its two dramatically different cell types, that has made *Caulobacter* a favorite organism for studying the mechanisms of cell cycle control, polarized differentiation and morphogenesis in bacteria.

2.1.1 CtrA – A Master Regulator of Cell Cycle Progression and Polar Morphogenesis

At the heart of the molecular machinery controlling *Caulobacter* morphogenesis is a protein called CtrA, a DNA-binding protein that functions as a transcriptional activator and repressor to regulate the expression of genes involved in DNA synthesis and cytofission, flagellar motility, and chemotaxis. CtrA is the final response regulator in a multicomponent phosphorelay system of the histidine protein kinase type that is universally found in bacteria and archaea, as well as in some eukaryotes (e.g. *Dictyostelium discoideum*). The phosphorylation cascade in such systems is initiated by an autophosphorylating histidine protein kinase, which is activated (or inhibited) by reception of a signal in the form of a ligand binding to its sensor domain. The phosphate is initially attached to a conserved histidine residue in the transmitter domain of the kinase, from where it is subsequently transferred (sometimes via multiple phosphotransfers) to an aspartate residue in the receiver domain of the same or a different protein – the response regulator that mediates the final response. In multicomponent systems, multiple phosphotransfers proceed from the primary histidine to the final aspartate via alternating histidine and aspartate residues in transmitter and receiver domains respectively of what can be distinct polypeptides.

The sequencing of the entire genome of *C. crescentus* made possible a comparative microarray analysis of gene expression in a wild type and temperature-sensitive *CtrA* loss-of-function mutant. Nearly 20% of the ca. 3700 genes in *Caulobacter* are cell cycle regulated and the microarray studies revealed that about one-third of these are controlled by CtrA, either directly or indirectly. Many of the direct targets were found by coimmunoprecipitation of DNA fragments that had been cross-linked to CtrA. This approach identified 55 promoters (regulating 95 genes) that bind and are presumably controlled by the active, phosphorylated form of CtrA (CtrA∼P). The binding site is a conserved nonameric DNA sequence motif that is found not only in CtrA-regulated promoters but also at five sites within the chromosomal origin of replication, *ori*. Binding of CtrA∼P to *ori* prevents the initiation of DNA synthesis and entry to S-phase. CtrA∼P also represses expression of the early cell division gene *ftsZ*, the product of which forms a ring that circumscribes the cell at the division site and assembles the cellular division proteins there at the inner face of the cytoplasmic membrane.

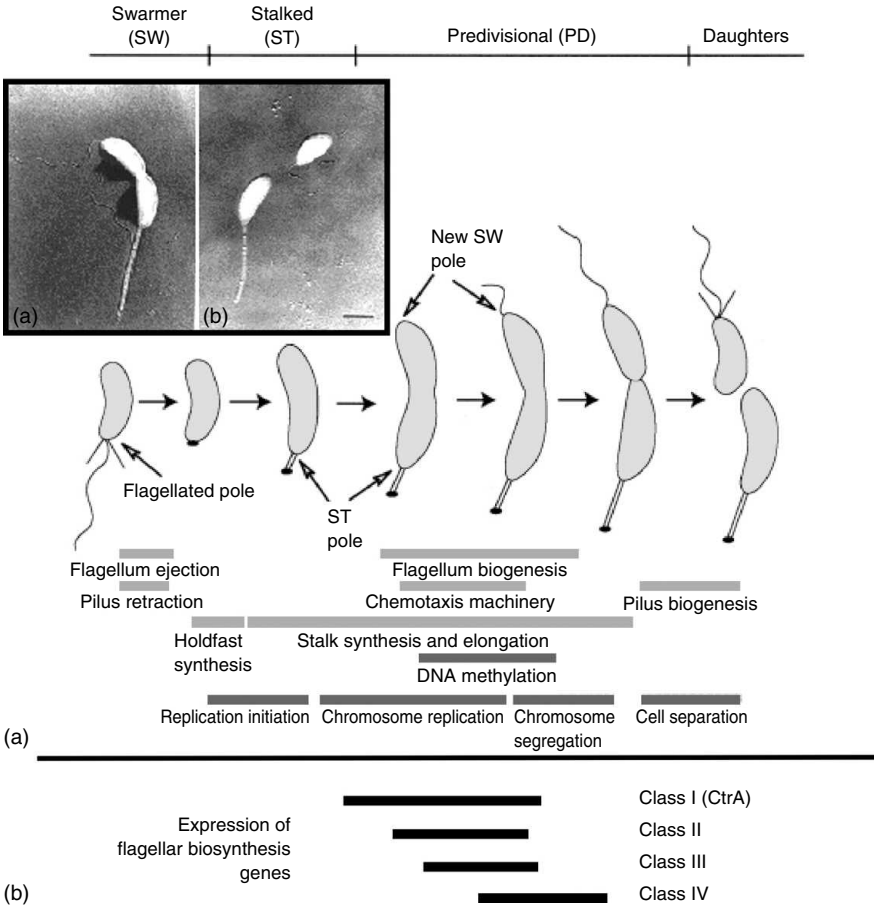

Fig. 1 The cell cycle and flagellar morphogenesis in *Caulobacter*. (a) The motile swarmer cell on the left loses its flagellum, retracts its polar pili and differentiates into a stalked cell, which enters the S-phase and progresses through the cell division cycle. The differentiation of two distinct daughter cells begins in the predivisional cell (inset, panel a) with distinct morphogenetic events occurring at the stalked (ST) and swarmer (SW) poles. After cytofission (inset, panel b), the stalked daughter cell is able to resume cell cycle progression, whereas the swarmer cell is arrested in growth phase (G1) until such time as it has differentiated into a stalked cell. The bars show the timing of various morphogenetic events during the cell cycle. (b) In the predivisional cell, a cascade of sequentially dependent inductions of flagellar gene expression and assembly events result in biogenesis of the flagellar apparatus at the swarmer pole. Horizontal bars show the timing of expression of the four sequentially induced classes of flagellar biosynthesis genes. Panel (a) is modified from Fig. 1 of Jacobs-Wagner, C. (2004) Regulatory proteins with a sense of direction: cell cycle signalling network in *Caulobacter, Mol. Microbiol.* **51**, 7–13. Panel (b) contains information presented in Fig. 1 of England & Gober (2001) Cell cycle control of morphogenesis in *Caulobacter Curr. Opin. Microbiol.* **4**, 674–680. Inset image courtesy of Jeanne S. Poindexter, Barnard College, Columbia University.

In keeping with its regulatory roles, the levels of CtrA in *Caulobacter* oscillate in synchrony with the cell cycle and differ in stalked and swarmer cells (Fig. 2). The levels of the phosphorylated form of CtrA change in concert with the levels of the protein itself. After accumulating in the late predivisional cell, CtrA∼P remains at high levels in swarmer cells where it represses cell cycle progression at the point of entry into S-phase and also induces the gene expression cascades involved in swarmer cell differentiation (e.g. those involved in pilus and flagellar assembly). In the stalked cell at the onset of replication, CtrA∼P levels are low, the protein having been both dephosphorylated and also degraded by ClpXP proteases. These two mechanisms of inactivating CtrA are redundant – mutant *ctrA* alleles that either are resistant to proteolysis or to inactivation by dephosphorylation are not lethal. The mutants progress through the cell cycle normally because in each case the alternative CtrA inactivation mechanism (dephosphorylation or degradation) is still present and is active at the appropriate cell cycle stage. As expected, a CtrA mutant that is both constitutively active and protease-resistant causes cell cycle arrest at the G1–S transition.

The disappearance and inactivation of CtrA at the end of G1 relieves its repression of replication, allowing the cell to enter S-phase and initiate DNA synthesis. Also relieved is the autoinhibitory repression of *ctrA* expression by high levels of CtrA∼P bound to the low affinity *ctrA* promoter, P1. The *ctrA* expression that results is autocatalytic because of CtrA∼P-mediated induction through a second, high affinity promoter, P2. Consequently, CtrA∼P levels rise again to high levels in the late predivisional cell, where they prevent

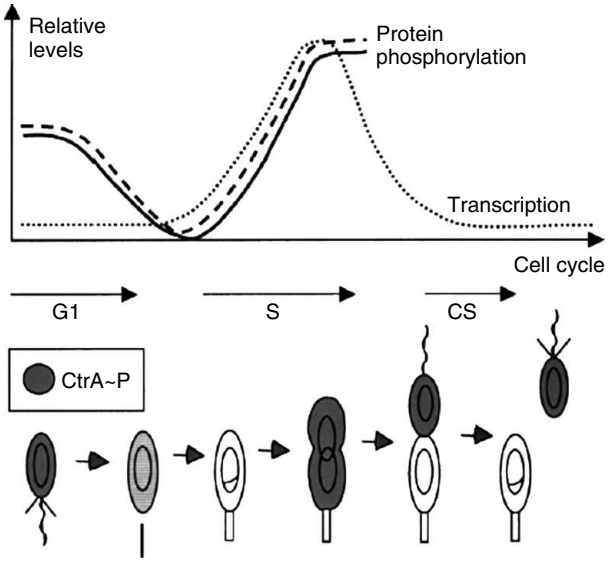

Fig. 2 Schematic representation of the regulatory mechanisms that modulate the level of CtrA∼P (in grey) during the cell cycle. From Fig. 2 of Ausmees, N., Jacobs-Wagner, C. (2003) Spatial and temporal control of differentiation and cell cycle progression in *Caulobacter crescentus*, *Annu. Rev. Microbiol.* **57**, 225–247.

initiation of another round of replication and again repress *ctrA* expression through the P1 promoter site.

2.1.2 Morphogenesis in the Swarmer Cell – Flagellar Biogenesis

Having accumulated in the predivisional cell, CtrA∼P persists in the swarmer cell, but is absent from the stalked cell. In the swarmer compartment of the predivisional cell, it initiates a gene expression cascade whose outcome is the differentiated swarmer cell and whose most obvious and best-understood feature is flagellar biogenesis. The ca. 50 gene products required for flagellar assembly in *Caulobacter* belong to four classes: Class I, the master regulator (CtrA); Class II, including a σ^{54} transcription factor (FlbD) and the first flagellar components to be assembled (the MS ring – FliF; the switch – FliG,M,N; the flagellum-specific secretion system – FlhH, FliI,J,O,P,Q,R); Class III, polypeptides forming outer parts of the basal body and hook; Class IV, the flagellar filament (Fig. 1).

Once initiated by CtrA∼P, the assembly of the flagellar apparatus proceeds in three major stages defined by the onset of supply of the requisite polypeptides encoded by the Class II, III, and IV genes. Within each stage, the assembly of the parts progresses in a sequentially dependent manner – the incorporation of each polypeptide depending upon the assembly of those before it. The start of each major assembly stage is defined by a checkpoint at which the synthesis of polypeptides for that stage can begin only if the preceding stage has been completed. Thus, the Class II genes are induced in the predivisional cell by CtrA∼P, the accumulation of which constitutes the Class I/II checkpoint.

The product of one of the Class II genes, *FlbD*, in its active phosphorylated form, in turn induces the Class III and IV genes in the swarmer pole of the predivisional cell. However, FlbD activity also depends upon two other Class II proteins – FlbE and FliX. FlbE was thought to be the kinase that phosphorylates FlbD, but recent evidence suggests that it activates FlbD by some other means. FliX functions as the checkpoint sensor that detects proper assembly of the inner parts of the flagellar basal body – FliX interacts directly with FlbD at its N terminus and only permits its activation when this Class II/III checkpoint has been reached. Active FlbD∼P not only induces the Class III and IV genes but it also feeds back to repress early Class II genes.

Although both Class III and Class IV genes are induced by FlbD∼P, the otherwise very stable Class IV mRNAs are targeted for degradation by the binding to them of the FlbT protein. This protein is present throughout the cell cycle, but its activity is inhibited by completion of the assembly of the flagellar motor, complete with hook. This constitutes the Class III/IV checkpoint. Only when this checkpoint has been reached are the Class IV mRNAs stabilized so that flagellin synthesis and completion of the entire flagellar apparatus can proceed.

2.1.3 Phosphorelays Regulating the Cell Cycle and Morphogenesis

CtrA is active only when phosphorylated at the conserved aspartate residue in its receiver domain (Asp51), and its activation by this means is controlled by at least three converging phosphorelay cascades (Fig. 3). The first of these involves CckA, a histidine protein kinase that is responsible for CtrA activation during the cell cycle. Consistent with its upstream role as a CtrA

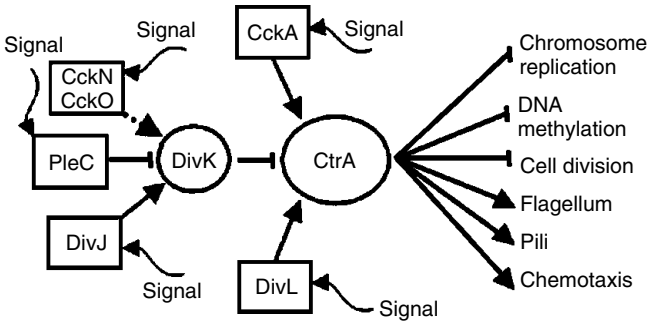

Fig. 3 Model of the signal transduction network controlling the activity of the master response regulator, CtrA. Response regulators and histidine kinases are shown as circles and boxes respectively. Barred ends indicate inhibition and arrowheads indicate activation. The dotted arrow indicates that the functions of the indicated upstream kinases are unknown. The molecular nature of the indicated signals that initiate the phosphorelays shown are unknown. Modified from Fig. 3 of Ausmees, N., Jacobs-Wagner, C. (2003) Spatial and temporal control of differentiation and cell cycle progression in *Caulobacter crescentus, Annu. Rev. Microbiol.* **57**, 225–247.

activator, CckA is essential for viability and temperature-sensitive mutants of this protein exhibit similar or identical phenotypes to temperature-sensitive CtrA mutants. However, CckA is rendered dispensable by expression of a constitutively active CtrA derivative (CtrAD51E) that does not require phosphorylation for activity. Because CckA contains its own response regulator receiver domain at its C terminus, it is anticipated that CckA passes phosphates to CtrA via an as yet unidentified intermediate histidine phosphotransferase in a multicomponent phosphorelay.

The second phosphorelay pathway regulating CtrA activity is mediated by DivL, a sensory kinase whose interactions with CtrA have been demonstrated genetically. Although it possesses all the conserved regions of the histidine kinase superfamily, DivL is unusual in possessing an autophosphorylatable tyrosine residue (Tyr550) instead of histidine. A cold sensitive *divL* allele is genetically suppressed (i.e. the wild-type phenotype is restored) by a specific *ctrA* allele (called *sokA*). This phenomenon of suppression is a classical genetic indicator of interactions between the corresponding encoded proteins. It is supported in this case by *in vitro* biochemical evidence that DivL can phosphorylate CtrA.

DivK is a response regulator protein that directly or indirectly controls the levels of active, phosphorylated CtrA, probably by accelerating both its dephosphorylation and its degradation by ClpX proteases. The cold-sensitive *divK341* allele causes cell cycle arrest at the G1–S transition – initiation of replication is blocked, genes involved in replication fail to be induced, and the ClpX-mediated degradation of CtrA does not occur. The upstream histidine kinases that regulate DivK include the nonessential proteins PleC and DivJ. *In vitro*, they can catalyze both the phosphorylation and the dephosphorylation of the response regulator DivK. However, their

in vivo actions appear to be opposed – DivJ phosphorylates and PleC dephosphorylates DivK so that its phosphorylation levels are reduced in a DivJ mutant, but increased in a PleC mutant. Two additional cytoplasmic histidine kinases of unknown function, CckN and CckO, have been identified in yeast two-hybrid screens as interacting partners of DivK.

The response regulator DivK and its upstream histidine kinases constitute the third phosphorelay cascade, leading to CtrA and regulating its activity. Just as the *sokA* allele of *ctrA* suppresses a conditional *divL* allele, it also suppresses mutant alleles of *divK, divJ*, and *pleC*. This provides a genetic demonstration of interactions between CtrA and the proteins encoded by these three genes. DivJ and PleC also interact with another response regulator protein, PleD, whose phosphorylated form activates proteolytic degradation of FliF, leading to loss of the flagella, transition to the stalked form, and entry to S-phase. The phosphorylated form of PleD is an active di-guanylate cyclase that synthesizes cyclic di-guanosine monophosphate (c-di-GMP) from 2 GTP molecules. In some other bacteria, this small molecule acts as an allosteric regulator activating cellulose synthase, but its downstream targets in *Caulobacter* are not known.

2.1.4 Dynamic Subcellular Localization of Phosphorelay Proteins Controlling Cell Division and Morphogenesis

Fusing the gene encoding jellyfish green fluorescent protein (GFP) with that for specific *Caulobacter* signaling proteins made it possible to use fluorescence microscopy to study their dynamic localization in living cells during the cell cycle (Fig. 4). Each of

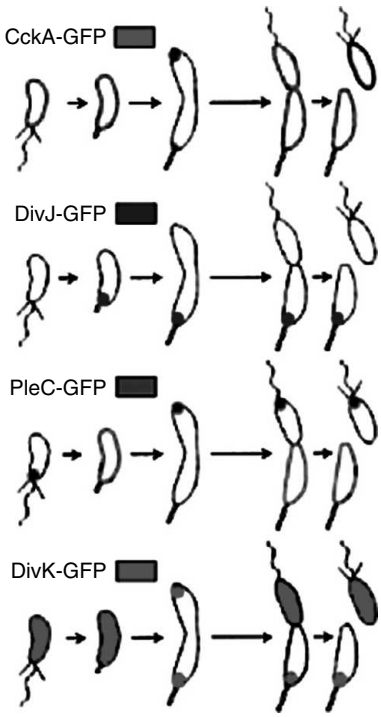

Fig. 4 Localization of some morphogenetic signaling proteins during the *Caulobacter* cell cycle. CckA and PleC are membrane-bound and cycle as shown between being dispersed throughout the membrane and concentrated at the indicated poles. DivJ, when present, is always concentrated at the stalked (ST) pole. DivK cycles between a diffuse cytoplasmic localization in swarmer cells and concentration at the indicated poles in predivisional and stalked cells. The length of the arrows indicates the time spent between each stage of differentiation. From Fig. 2 of Jacobs-Wagner, C. (2004) Regulatory proteins with a sense of direction: cell cycle signalling network in *Caulobacter*, *Mol. Microbiol.* **51**, 7–13. (See color plate. p. xxix)

these signaling proteins exhibits a characteristic pattern of localization that reflects its functions in morphogenesis and cell division. From being dispersed throughout the inner, cytoplasmic membrane, CckA translocates in the predivisional cell to the poles, particularly the swarmer pole where it can phosphorylate CtrA and initiate flagellar assembly. It returns to its original diffuse membrane distribution by the time cell division is complete. DivK translocates from the cytoplasm in the swarmer cell to both poles in the predivisional cell where it is regulated by either DivJ (at the stalked pole) or PleC (at the swarmer pole). By the time division is complete, DivK has been released from its polar location in the swarmer cell to return to its original distribution. However, it remains localized at the stalked pole in the stalked cell. At the stalked pole DivJ would activate DivK and so promote dephosphorylation and degradation of CtrA, favoring progression through the cell cycle. During early differentiation of the stalked cell, PleC is released from the newly forming stalked pole and moves to the opposite pole where it would keep DivK inactive and CtrA active in inducing flagellar biogenesis.

What controls these very striking localization patterns? For the most part, the answer to this question is not yet known, but some elements of the mechanisms involved have emerged. Firstly, correct polar localization of DivK depends upon phosphorylation of its conserved receiver aspartate and recruitment by DivJ at the stalked pole. Secondly, DivK release from the swarmer pole requires PleC, presumably because of the PleC-mediated dephosphorylation of DivK. Thirdly, the release of PleC itself from the future stalked pole requires PleC's own catalytic activity, while its localization to the swarmer pole requires a protein with similar localization patterns called *PodJ*. Fourthly, a 61-residue sequence in the cytoplasmic linker region of the sensor domain of DivJ has been shown to be necessary for its proper localization. Finally, the localization of all of these proteins to the correct pole depends on MreB, a bacterial homolog of the eukaryotic cytoskeletal protein, actin. MreB forms a filament that oscillates during the cell cycle between a spiral form running the length of the cell and a medial ring. The ring could be an intermediate in a reversal of polarity of the spiral as the flagellated swarmer pole matures into a stalked pole.

Clearly, although much remains to be elucidated, the correct localization of signaling proteins in *Caulobacter* morphogenesis both controls and is itself dependent upon the phosphorelay cascades in which these proteins participate.

2.2 Sporulation and Differentiation in *Bacillus subtilis*

Caulobacter is not the only bacterium that differentiates into two cell types. Under conditions of high population density and starvation, many Gram-positive bacteria belonging most notably to the genera *Bacillus* (aerobic) and *Clostridium* (anaerobic) can differentiate to form an endospore enclosed within a mother cell, which subsequently perishes. The endospore is an extremely heat- and dessication-resistant quiescent cell that is of medical significance because some endospore-forming bacteria of both genera are human pathogens (e.g. *Bacillus anthracis*, causative agent of anthrax, and *Clostridium tetani*, causative agent of tetanus). It is the extreme resistance properties of bacterial endospores that determine the minimum

requirements for successful sterilization of culture media, equipment, and surgical instruments. Phylogenetic studies have shown that the important signaling interactions and central mechanisms for sporulation are conserved amongst all endospore-forming bacteria. What seems to change the most in different lineages is the sensor domains of the receptor kinases that transmit relevant environmental information to the cells. This implies that different environmental signals relevant to endospore formation are monitored by the different species – as might be expected given the very varied habitats in which they live, including oil wells, salt lakes, soil, or infected mammalian hosts. Endospore formation has been most intensively studied in the saprophytic soil bacterium, *Bacillus subtilis*.

When *B. subtilis* cells reach a stationary phase, they enter a so-called transition state in which they must choose between several possible survival strategies – endospore formation, nutrient scavenging, and transformation. Nutrient scavenging is the strategy of first choice and involves expression of genes for chemotaxis toward nutrient sources, secretion of antibiotics that inhibit competitors, and the secretion of extracellular enzymes, such as proteases, that degrade environmental macromolecules into their constituents for uptake as nutrients. If the adverse conditions that elicit the nutrient scavenging strategy persist, but do not worsen significantly, 1–10% of the cells will opt for the transformation strategy. This involves the cell differentiating to become competent for the uptake of exogenous DNA (released into the environment by the lysis of other cells). This can lead to the formation of recombinant cells with new combinations of genetic information that could enhance survival. Because endospore formation is a complex energy-intensive process, the cell only commits itself to this path as a last resort in response to integrated information from multiple environmental and physiological signals. These signals converge on the phosphorylated form of a master regulator protein, Spo0A∼P, whose levels determine whether the cell enters the sporulation pathway or not. At intermediate Spo0A∼P levels, only the nutrient scavenging and (in some cells) transformation strategies are pursued. When

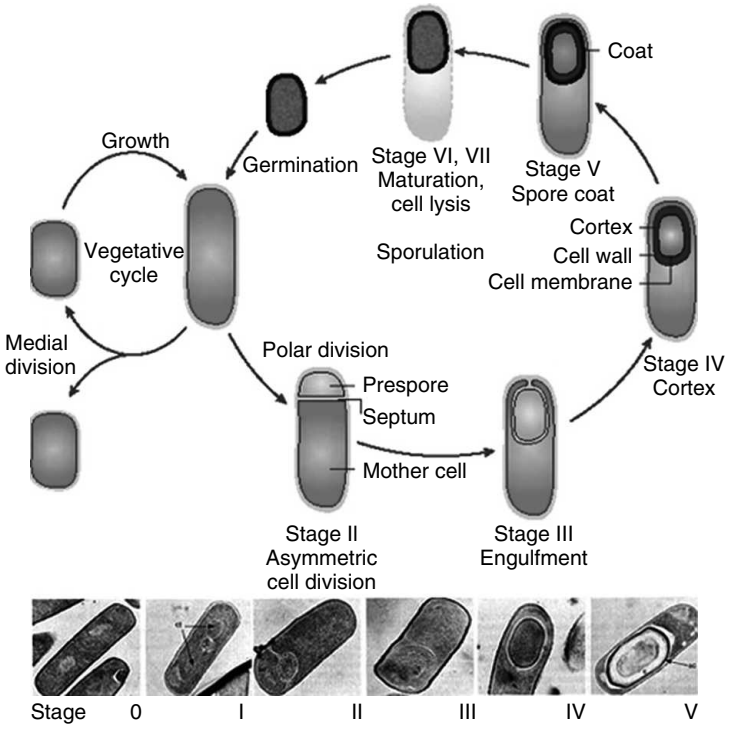
Fig. 5 The key stages of the sporulation cycle in *Bacillus subtilis* (from Fig. 1 of Errington, J. (2003) Regulation of endospore formation in *Bacillus subtilis, Nat. Rev. Microbiol.* **1**, 117–126). The inset (from ''Todar's Online Textbook of Bacteriology'', http://www.textbookofbacteriology.net/ Kenneth Todar, 2002) shows electron micrographs of sporulating cells at each of the major stages. The formation of endospores is a complex and highly regulated form of development in a relatively simple (procaryotic) cell. In all *Bacillus* species studied, the process of spore formation is similar, and can be divided into seven defined stages (0–VI). The vegetative cell (Stage 0) begins spore development when the DNA coils along the central axis of the cell as an ''axial filament'' (Stage I). The DNA then separates and one chromosome becomes enclosed in plasma membrane to form a protoplast (Stage II). The protoplast is then engulfed by the mother cell membrane to form a intermediate structure called a *forespore* (Stage III). Between the two membranes, the core (cell) wall, cortex, and spore coats are synthesized (Stage IV). As water is removed from the spore and as it matures, it becomes increasingly heat resistant and more refractile (Stage V). The mature spore is eventually liberated by lysis of the mother cell. The entire process takes place over a period of 6 to 7 h and requires the temporal regulation of more than 50 unique genes. Inset image and description of the stages were kindly provided by Kenneth Todar.

Spo0A∼P reach high-enough levels, cells will abandon the nutrient scavenging strategy, forego the transformation strategy, and sporulate (see Fig. 5).

2.2.1 Spo0A and the Phosphorelay in Endospore Formation

In Fig. 6, which shows the basic outline of the sporulation phosphorelay mechanism, a sensor histidine-kinase autophosphorylates the conserved histidine in its transmitter domain and then passes this phosphate to an aspartate in the receiver domain of Spo0F. The phosphate is then passed via a histidine in Spo0B to an aspartate residue in the receiver domain of Spo0A, the final response regulator. Although only one sensor kinase is shown in Fig. 6, there are in fact five different sensor kinases (KinA to KinE) in *B. subtilis* that send signals into this phosphorelay (Fig. 7). The two most important of these, in order of significance, are KinA and KinB. The other kinases on their own seem to be able only to generate intermediate levels of Spo0A∼P, sufficient for the nutrient scavenging and competence pathways, but insufficient to induce sporulation. Although it is clear that sporulation is initiated primarily by starvation and high cell density, the molecular identities of the signals to which the sensor kinases respond are unknown.

Spo0A∼P is an active DNA-binding protein that can function either as a positive or a negative regulator of transcription and has been shown in recent microarray studies to induce, directly or indirectly, the transcription of 349 genes (66 of them in combination with the sigma factor σ^F).



The *spoIIA, spoIIG*, and *spoIIE* promoters are amongst those that are directly induced by Spo0A∼P, and the corresponding gene products play essential roles in Stage II of sporulation (see later). These genes are also induced indirectly by Spo0A∼P via SinI. The synthesis of SinI is induced by Spo0A∼P, and, once made, SinI interacts with SinR, preventing it from repressing its target genes.

SpoA∼P also directly or indirectly represses expression of as many as 242 different genes, including *abrB*, which encodes a transcriptional repressor. AbrB is responsible for repressing stationary phase and sporulation functions during

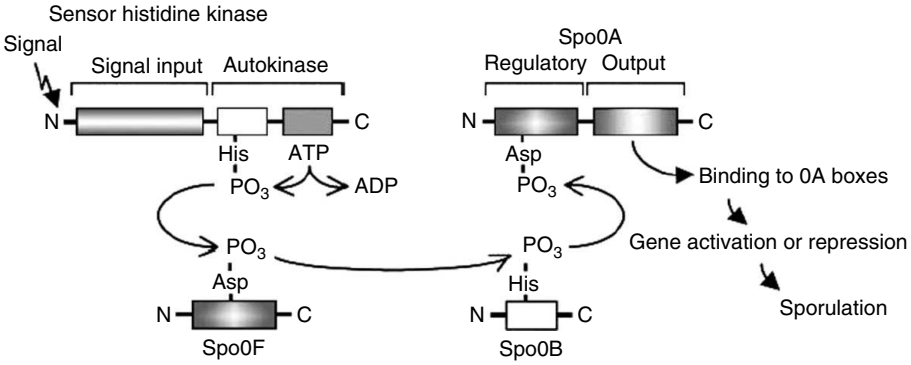


Fig. 6 The *Bacillus subtilis* sporulation phosphorelay (from Fig. 1 of Stephenson, K., Hoch, J.A. (2002) Evolution of signalling in the sporulation phosphorelay, *Mol. Microbiol.* **46**, 297–304).

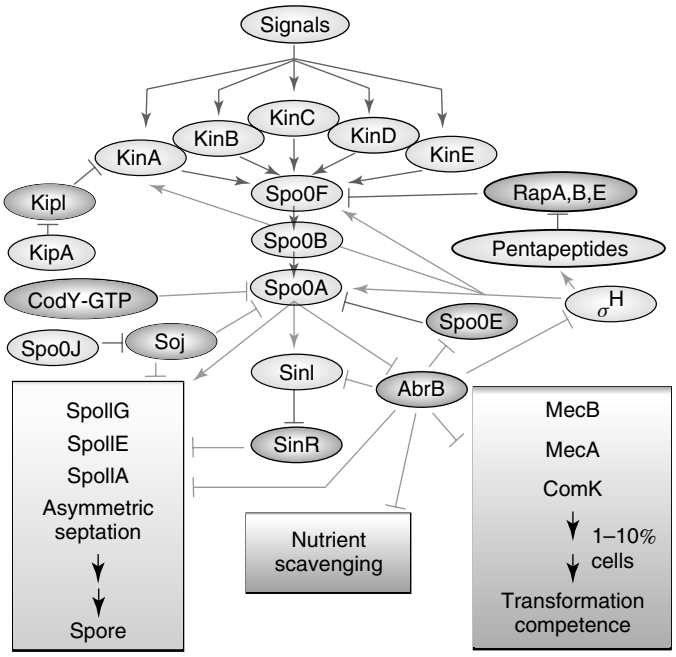

the growth phase. Its targets are upregulated by Spo0A∼P indirectly by removal of AbrB-mediated repression. One of these target genes, *spo0H*, encodes the sigma factor σ^H, which targets RNA polymerase to at least 49 promoters controlling at least 87 early sporulation genes. These include the *kinA* promoter and secondary, highly active promoters for *spo0F* and *spo0A*. By this means, a positive feedback is established that results in a new, higher level of Spo0A∼P, committing the cell to sporulation.

The phosphorelay leading to Spo0A∼P accumulation in stationary phase cells is subject not only to the positive controls described but also to negative controls that prevent the cell from committing to sporulation inappropriately or prematurely. There are several such negative control mechanisms.

The first mechanism for limiting Spo0A∼P accumulation is mediated by cellular GTP levels, which serve as the main indicator of the status of intermediary metabolism. During growth, GTP levels are high (1–3 mM), but they drop significantly upon entry to the stationary phase. Two proteins have been implicated in sensing GTP levels – CodY (early stages) and Obg (later stages). CodY in its GTP-bound form is a repressor of stationary phase/sporulation genes including *spo0A*.

The second mechanism for restraining Spo0A∼P accumulation is by the action of Spo0E, a phosphatase that specifically dephosphorylates Spo0A∼P. Without Spo0E, Spo0A would become maximally phosphorylated even at low levels of activity of the phosphorelay. Spo0E expression is subject to AbrB-mediated repression.

The third mechanism for restricting Spo0A phosphorylation is mediated by pentapeptide pheromone signals. The precursors of the pentapeptides are small polypeptides of about 40 amino acids that are secreted and processed proteolytically outside the cell, then imported via specific transport systems (products of the *opp* and *app* operons) into the cell where they inhibit the Rap family phosphatases RapA, B, and E. The extracellular concentrations of the signaling pentapeptides depend upon the density of stationary phase cells, so that only at high cell density do they prevent the dephosphorylation of Spo0F and thereby allow unrestrained phosphorelay to produce maximum Spo0A∼P levels.

Fig. 7 Regulation of the phosphorelay and the initiation of sporulation in *Bacillus subtilis*. During the growth phase, AbrB represses genes involved in the three stationary phase survival strategies (boxed) – sporulation, nutrient scavenging, and transformation. At the onset of stationary phase, multiple signals result in activity of the phosphorelay, producing intermediate levels of phosphorylated Spo0A. These levels of Spo0A∼P are sufficient to support the nutrient scavenging and, eventually, in some cells the transformation strategy for survival. Under more extreme circumstances of nutritional stress and high density, several positive feedbacks can combine with the lifting of several negative restraints to elicit production of high levels of Spo0A∼P. At these high levels, the expression of sporulation-specific genes is induced and the cell progresses down the pathway of endospore formation. Green ellipses indicate proteins whose activity stimulates the phosphorelay, while red ellipses indicate proteins whose activity inhibits it. Arrowheads indicate stimulatory interactions and barred ends indicate inhibitory interactions. Blue arrows stand for interactions at the transcriptional level (gene induction or repression) and red arrows stand for interactions at the protein level (activation or inhibition). MekR, MekB, and ComK are AbrB-repressible proteins involved in the development of transformation competence. Other proteins are described in the text. (See color plate. p. xxx)

The fourth mechanism for limiting the activity of the sporulation phosphorelay is inhibition of the KinA kinase by the KipI protein, which is itself antagonized by KipA. The expression of KipI and KipA is controlled by carbon and nitrogen sources, so that phosphorelay is inhibited by the availability of nutrients and the cell persists with the nutrient scavenging strategy rather than sporulate.

The fifth mechanism by which Spo0A∼P levels are limited is by Soj-mediated repression of expression of *spo0A*. Soj also represses the *spoIIA,E* and *G* operons, which are targets for Spo0A∼P induction and its repressive activity is antagonized by Spo0J. During growth, the interaction between Spo0J and Soj serves what appears to be a completely different function in partitioning chromosomes into daughter cells. However, these disparate roles may be intimately connected – during sporulation Spo0J is required to localize Soj at the poles, probably in association with the chromosomal origin of replication *oriC*. Key *spo* promoters elsewhere may be liberated from Soj repression by this means, which could thus constitute a final checkpoint, delaying progression of sporulation until the chromosome has been replicated and the *oriC* regions have segregated.

2.2.2 Mother–Daughter Communication in Endospore Formation – A Spatiotemporally Regulated Sigma Factor Cascade

Once the cell has embarked on endospore formation as a result of the accumulation of high enough levels of Spo0A∼P, a gene expression cascade is induced, which is coupled to morphogenetic events such as septation to form the forespore and its subsequent engulfment by the mother cell. This gene expression cascade is orchestrated by timed, serially dependent expression of specific sigma factors, each of which associates in turn with the RNA polymerase core enzyme, targeting it to a specific set of promoters (Fig. 8). The first of the sigma factors to be induced are σ^E and σ^F, whose genes belong to the *spoIIG* and *spoIIA* operons respectively (Fig. 7). Both proteins are synthesized prior to septum formation in an inactive form, and both operons also encode proteins that regulate the activities of their cognate sigma factors. Only after septum formation do these two sigma factors become active – σ^E in the mother cell and σ^F in the forespore.

Septum formation is thus a critical event in orchestrating other events in spore formation, and only when the septum has formed is the cell irrevocably committed to sporulation. The formation of the septum is a specialized cell division event that uses much of the same cellular machinery as normal cell fission, including the FtsZ ring, which forms, in this case, not at the middle of the cell, but near one end. FtsZ is one of the proteins whose synthesis is induced directly by Spo0A∼P and the resulting rise in its cellular concentration is necessary for ring formation during sporulation. During sporulation, FtsZ initially forms two rings located near the cell poles, one of which (usually the larger) is subsequently ''selected'' for septum formation. SpoIIE, a protein phosphatase also necessary for σ^F activation (see later), is required for correct placement of the ring. There, as in normal cell division, FtsZ acts as a scaffold for recruitment of other cell division proteins to the division site and possibly as a GTP-powered contractile structure.

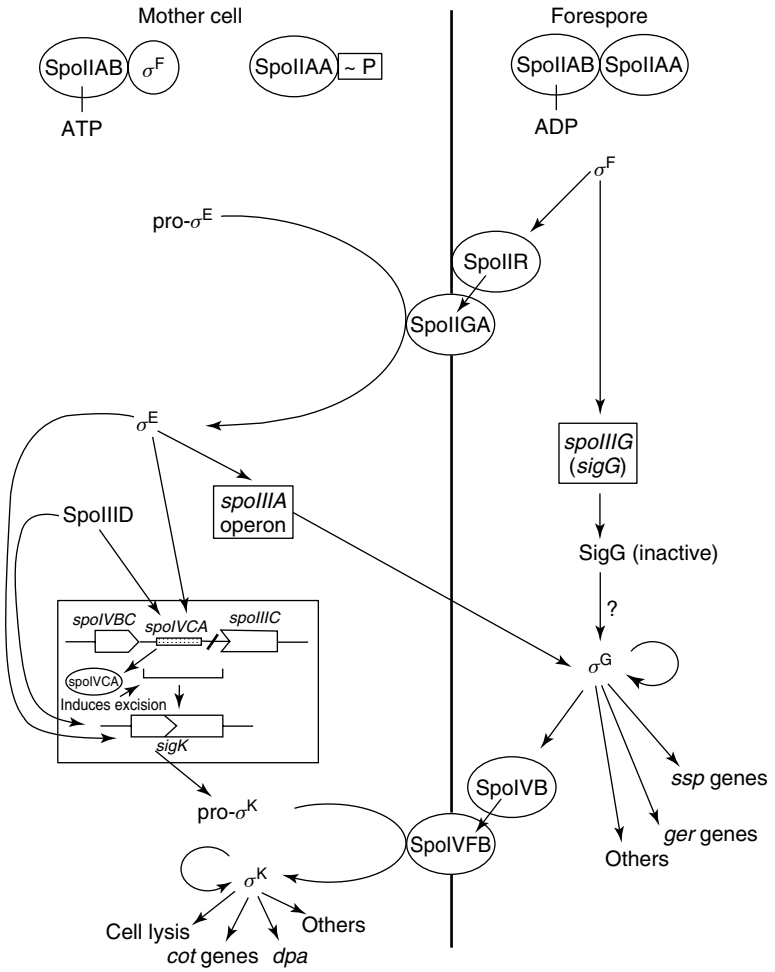

Fig. 8 The mechanisms involved in the regulation of sigma factors in the compartmentalized sporulating cell. The symbol σ and appropriate letter indicates the sigma factors, and precursor proteins of these sigma factors are indicated as pro-σ and the appropriate letter. The status of sigma F (σ^F) in each compartment post septation is indicated at the top of the figure. A vertical line represents the asymmetric septum, which divides the mother cell and the forespore. Arrows indicate activation. Circular arrows indicate autoregulation. Those proteins associated with the membrane are illustrated as embedded in the septum. Unknown regulatory mechanisms are indicated with a question mark. From Fig. 2 of Phillips, Z.E.V., Strauch, M.A. (2002) *Bacillus subtilis* sporulation and stationary phase gene expression, *Cell. Mol. Life Sci.* **59**, 392–402.

With the FtsZ ring in place, septation proceeds by a process of membrane invagination and initial synthesis of some cell wall material, which is later removed (this lends support to the idea that spore formation evolved as a modified form of normal cell division). Septation is complete before the entire forespore chromosome has been

segregated to the spore compartment. During chromosome segregation, the chromosomal origin of replication, *oriC,* is translocated and anchored to the poles by a mechanism that is not understood, but involves several proteins – DivIVA, Spo0J, Soj, and RacA. However, only about 30% of the chromosome, centered around *oriC,* is initially located within the forespore. The rest is subsequently transported there from the mother cell over a period of 10 to 15 min by a DNA translocase, SpoIIIE. It is during this brief period when the forespore is bereft of about two-third of the genes, while the mother cell has two copies of them, that some of the critical asymmetries between mother and forespore are established. These asymmetries cause the two cells to embark on different programs of gene expression, as shown in Fig. 8.

One such asymmetry arises from the location of the SpoIIA operon on the opposite side of the chromosome from *oriC*. SpoIIAB is an antisigma factor (and protein kinase), which, in the mother cell, is bound to σ^F, keeping it inactive. However, SpoIIAB is labile so that its concentration drops rapidly in the forespore in the period before delivery of the SpoIIA operon to that compartment. This would result in activation of σ^F only in the forespore. The second, and perhaps the most important asymmetry, is that the SpoIIE protein phosphatase, which is associated with the division machinery, is delivered into the forespore after septation by a SpoIIIE-dependent mechanism. There it dephosphorylates the protein SpoIIAA in opposition to the kinase activity of SpoIIAB. Dephosphorylated SpoIIAA displaces σ^F from its complex with SpoIIAB, so that the sigma factor is free to associate with RNA polymerase. The combined effects of increased SpoIIE and decreased SpoIIAB concentrations in the forespore thus result in the activation of σ^F-mediated gene transcription there, but not in the mother cell.

Amongst the genes whose transcription is directed by σ^F is *spoIIR* whose gene product is secreted into the intermembrane space of the septum bounded by the forespore and mother cell membranes. There it activates the SpoIIGA protease, an integral membrane protein located in the septal membrane of the mother cell. On the mother cell side of the membrane, the activated SpoIIGA proteolytically cleaves pro-σ^E to release active σ^E and so initiates σ^E-dependent gene expression in the mother cell.

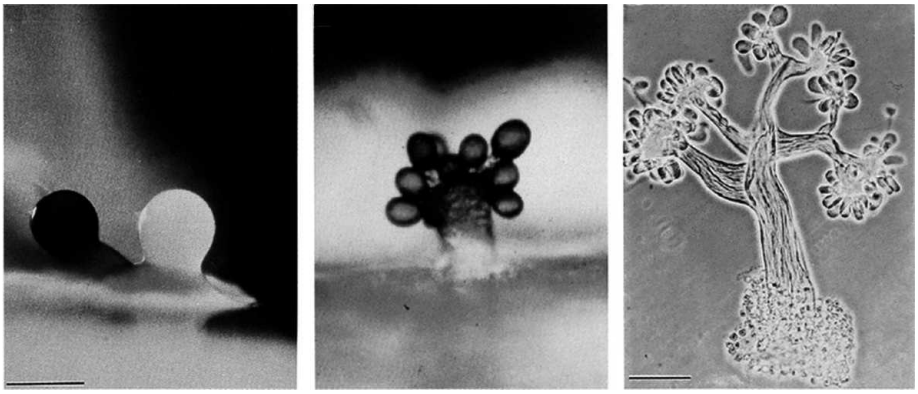
Another of the σ^F-dependent genes expressed in the forespore is *spoIIIG*, which encodes σ^G, the next sigma factor to be deployed in the forespore. However, σ^G is also synthesized in an inactive form. Its activation depends upon the proteins encoded in the *spoIIIA* operon transcribed only in the mother cell by σ^E-directed RNA polymerase. The SpoIIIA proteins are initially located in the mother cell septal membrane and, after engulfment, are found in the topologically equivalent outer forespore membrane. How, from this location, they activate σ^G is unknown, but having been thus activated, σ^G directs the transcription of a suite of genes in the forespore involved in spore maturation and germination. Amongst the σ^G-dependent genes is *spoIVB* whose protein product in the forespore somehow sends a signal to activate the SpoIVFB protease that resides in the mother cell septal membrane in an inhibitory complex with SpoIVFA and BofA.

The role of the activated SpoIVFB protease in the mother cell membrane is to activate the final mother cell–specific sigma factor, σ^K, encoded by *sigK*. Expression of *sigK* depends upon σ^E in two ways. Firstly, *sigK* is transcribed from a σ^E-driven promoter. Secondly, *sigK* in many

Bacillus strains is interrupted by a 48-kbp element called *skin* that is excised precisely by a site-specific recombinase (SpoIVCA) whose expression also depends on σ^E (as well as on SpoIIID). SpoIVCA is encoded within the *skin* element itself. Transcription in the mother cell from σ^K-driven promoters results in the assembly of the outer spore coat and production of dipicolinic acid, which is accumulated as its calcium salt by the maturing spore to very high concentrations and is responsible for many of its essential resistance properties. Some of the σ^K-dependent gene products are also responsible for the eventual lysis of the mother cell – a form of programmed cell death – that occurs after spore maturation is complete.

2.3 Differentiation and Morphogenesis in *Myxococcus xanthus*

Caulobacter differentiation occurs as part of the growth cycle and does not depend upon the presence of neighboring cells, whereas sporulation in *Bacillus* is initiated under starvation conditions at high cell densities when growth is no longer an option. The social bacterium *Myxococcus xanthus* takes this cooperativity one step further in its foraging behavior and fruiting body formation. *M. xanthus* is one species of the myxobacteria, gliding bacteria that live in soil environments and, under conditions of starvation and high density, aggregate together to form true multicellular structures that contain resistant, dormant spores (Fig. 9). *Myxococcus* cells exhibit two different forms of gliding motility that can be separated genetically and are mediated by completely different mechanisms. Adventurous or A motility is exhibited by isolated cells, while social or S motility requires close association between cells and is exhibited only in groups. The mechanism of A motility is still not understood. S motility is mediated by extension and retraction of Type IV pili and also requires the lipopolysaccharide



(a) (b) (c)

Fig. 9 Fruiting bodies of myxobacteria. (A) *Myxococcus fulvus*. Phase contrast. Bar, 50 mm. (B) *Stigmatella aurantiaca*. Phase contrast. Fruiting body is about 150 mm tall. (C) *Chondromyces crocatus*. Slide mount, phase contrast. Bar, 100 mm. *Myxococcus xanthus* fruiting bodies are similar in morphology (but not pigmentation) to those of *M. fulvus*. From Fig. 1 of Dworkin, M. (1996) Recent advances in the social and developmental biology of the myxobacteria, *Microbiol. Rev.* **60**, 70–102.

O-antigen on the cell surface as well as polysaccharide/protein appendages called *fibrils*. During growth, S motility allows *M. xanthus* cells to migrate together in groups and prey on other bacteria by secreting enzymes that lyse and digest the macromolecules of their victims. This so-called ''wolf pack'' behavior supports faster growth because of the cooperative effect of many cells secreting the necessary lytic enzymes. Under starvation conditions, S motility allows myxobacteria to aggregate and form fruiting bodies, within which a proportion of the cells differentiate into round myxospores. Mutants deficient in S motility are therefore unable to aggregate and sporulate.

2.3.1 Initiation of Development by Starvation and Extracellular Signals

The primary signal that initiates development in *M. xanthus* is starvation. As in other bacteria, this elicits the so-called *stringent response*, whereby nutritional stress is sensed by the stalling of protein synthesis and accompanying activation of RelA, the ribosome-associated (p)ppGpp synthase. The resulting increase in (p)ppGpp concentrations regulates transcription, leading to decreased rRNA synthesis, cessation of growth, and increased expression of early developmental genes. Amongst these are genes encoding proteins whose activity leads to production of extracellular developmental signals (morphogens) that accumulate and thus convey cell density information to the developing myxobacteria.

The extracellular signals controlling early development were originally discovered genetically by testing the ability of pairs of nondeveloping mutants to restore one another's ability to develop normally when mixed together. This phenomenon was called *extracellular complementation* by analogy with genetic complementation in which two different mutant genomes are mixed within a cell (by appropriate genetic crosses) and tested for restoration of normal behavior. Extracellular complementation tests of pairwise combinations of mutants revealed five distinct groups, A to E. Whereas mixtures of cells from different mutants within the same group were unable to form fruiting bodies, mixtures of mutants from different groups could undergo normal development. These results indicated that mutants within each extracellular complementation group were deficient in the production of a specific extracellular factor or signal that could still be supplied by mutants from a different group.

The mutants within each group have been found to express developmentally regulated genes normally up to a characteristic time in development. Development was arrested at this time point, which therefore represented the time at which the extracellular signal missing in that group would normally have been deployed. Thus, the order of action in development of the five extracellular signals was found to be B, A, D, E, and C (Fig. 10).

The mutant genes associated with the extracellular complementation groups in *M. xanthus* have been identified and, in some cases, provide clues to the identity of the corresponding signal. The genes in the A group are *asgA*, *B*, *C*, and *D*. Two of these (*asgA* and *asgD*) encode histidine protein kinases with both kinase and response regulator domains. AsgB is a putative transcription factor with a helix-turn-helix DNA-binding motif near its C terminus, while AsgC is the RNA polymerase sigma factor σ^{70} (also known as SigA or RpoD). AsgA and/or D could directly or indirectly sense the accumulation of the alarm molecule (p)ppGpp and activate AsgB-

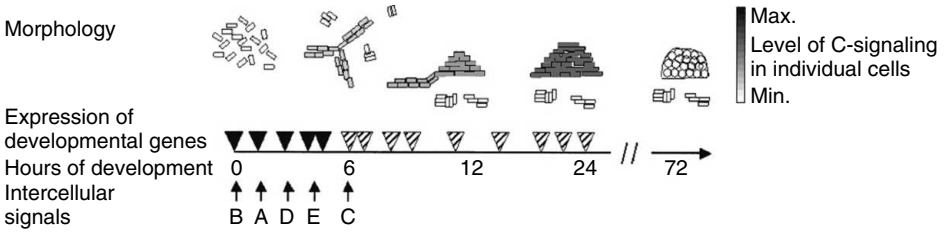


Fig. 10 Multicellular morphogenesis in *Myxococcus xanthus*. On the developmental timeline, the black triangles indicate the expression time of developmental genes expressed in all cells before the initiation of C-signaling; the hatched triangles indicate the expression time of C-signal-dependent genes, all of which are only expressed in sporulating cells. The time of action of the A to E signals is indicated by the arrows below the timeline. Cellular arrangements during the different stages of fruiting body formation are shown above the timeline. The grayscale coloring of cells according to the intensity profile shown on the right indicates the level of C-signaling in individual cells during the different morphological stages. At 72 h, cells inside the fruiting bodies have matured to spores, and the cells remaining outside the fruiting bodies are the peripheral rods. From Fig. 1 of Søgaard-Anderson et al. (2003) Coupling gene expression and multicellular morphogenesis during fruiting body formation in *Myxococcus xanthus*, *Mol. Microbiol.* **48**, 1–8.

and AsgC-directed transcription of genes encoding the extracellular proteases that produce the A-signal. These extracellular proteases are secreted and hydrolyze cell surface proteins whose constituent amino acids accordingly increase locally in concentration to an average of about 25 μM. This is insufficient to support growth, but sufficient for a subset of six amino acids (tryptophan, proline, phenylalanine, tyrosine, leucine, and isoleucine) to jointly constitute the A-signal. Proteins involved in transducing the A-signal include SasS, a histidine kinase, and SasR, its cognate response regulator.

Apart from the A-signal, the best understood of the five extracellular *M. xanthus* developmental signals is the C-signal. The processed product of the only C group gene, *csgA*, the authentic C-signal appears to be the 17-kD C-terminal portion of the 25-kDa CsgA protein. CsgA is secreted by developing *M. xanthus* cells and processed by an extracellular protease to produce the active C-signal. The full length CsgA protein shares homology with short chain alcohol dehydrogenases (SCADs), its N-terminal region containing the NAD^+-binding motif and the C-terminal portion containing the catalytic domain. The absence of the NAD^+-binding site from the active C-signal suggests that the protein's putative enzymatic activity does not play a role in its C-signaling capabilities. Exogenous addition of both the active, N-terminally truncated form, and the full-length form of CsgA are able to rescue development in C-group mutants, the full-length form doing so by first being clipped by extracellular proteases, as in normal development.

The three remaining extracellular signals (B, D, and E) are less well characterized. The only gene in the B group is *bsgA*, which encodes a protein sharing homology with the *Escherichia coli* Lon protease. The nature of the B-signal is still not understood, but its generation requires the BsgA protein and so may depend, directly or indirectly, on a proteolytic event. As is the case with A-signal transduction, a

histidine kinase (SpdS) and response regulator (SpdR) pair are involved in B-signal transduction. The only gene in the D group is *dsgA*, which encodes an initiation factor for translation, IF3. Point mutations in *dsgA* reduce the efficiency of sporulation, but do not completely prevent it, while disruption of the gene is lethal. Presumably, the generation of the D-signal depends more sensitively than other cellular functions on some aspect of IF3 activity in translation initiation. The generation of the E-signal depends upon two *esg* genes, which encode the E1α and E1β subunits of branched-chain keto acid dehydrogenase. This enzyme produces coenzyme A-linked forms of the fatty acids isovalerate, methyl butyrate, and isobutyrate, suggesting the possibility that these short-chain-branched fatty acids might constitute the E-signal. Consistent with this, the defect in E-group mutants can be rescued by exogenous supply of isovalerate.

2.3.2 C-signal Transduction and Sporulation After Aggregation

Four of the five *Myxococcus* morphogenetic signals are involved in early development – the first 6 h after the onset of starvation, during which time there is little overt morphological change in the lawn of starving bacteria. After six h of development, the cells begin to aggregate to form mounds that will develop into mature fruiting bodies. This change and the associated shifts in gene expression patterns are initiated by the C-signal. Although C-signal can rescue development in *csgA* mutants when supplied exogenously in solution, transmission of the C-signal between cells during normal development depends on direct end-to-end cell contacts because CsgA (full length and clipped) is membrane-bound and (presumably) localized at the poles. Such end-to-end contacts between cells are more frequent in aggregating streams of cells and most frequent within mounds, so that the aggregation process results in an ordered increase in the level of C-signaling and provides a link between it and the stage of morphogenesis that has been reached.

C-signal transduction pathways lead from an unidentified receptor(s) to three different responses in the cells that are separated in space and time – C-signal amplification, aggregation, and sporulation in mounds (Fig. 11).

The first of the three C-signaling pathways leads to heightened induction of transcription of *csgA* and so to an increase in the level of C-signal. The proteins encoded by the *act* operon, ActA to D mediate this response. ActA is a histidine kinase and ActB is its cognate response regulator that activates *csgA* transcription, while ActC and D somehow control the correct developmental timing of *csgA* expression. A consequence of this positive feedback is that the level of C-signaling continues to increase once it has been initiated.

The second of the C-signal-mediated responses is aggregation and, as noted above, it also feeds back to increase the level of C-signaling by increasing the frequency of end-to-end contacts between cells. The earliest recognized component in the transduction pathway leading to aggregation is the activation (possibly by phosphorylation) of FruA, a DNA-binding response regulator whose expression was induced earlier in development by the A- and E-signals. FruA, in turn, activates the Frz chemotaxis-like signaling system and this leads to aggregation. The Frz proteins include homologs of the major chemotaxis-signaling proteins in *E. coli*. FrzCD is a methyl-accepting chemotaxis protein (MCP) homolog whose role is presumed to be analogous to the MCPs

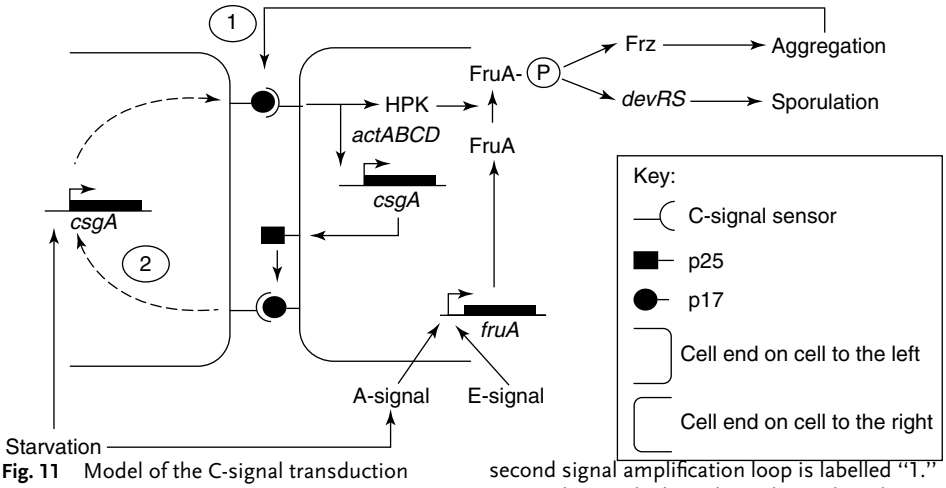

Fig. 11 Model of the C-signal transduction pathway. The schematic illustrates the C-signal transmission between two neighboring cells. For simplicity, the components in the pathway are only shown in the cell on the right. These components are also present in the cell on the left. In this cell, only *csgA* is shown to illustrate the signal amplification loop labelled "2." The second signal amplification loop is labelled "1." HPK indicates the hypothetical FruA histidine protein kinase. Modified from Fig. 2 of Søgaard-Anderson et al. (2003) Coupling gene expression and multicellular morphogenesis during fruiting body formation in *Myxococcus xanthus*, *Mol. Microbiol.* **48**, 1–8.

of *E. coli*, which function as receptors and transmembrane signal transducers. However, FrzCD differs from them in being a soluble, cytoplasmic protein, implying that the signals to which it directly responds must be intracellular, having either entered the cell or been produced in response to an extracellular signal. Cytoplasmic MCPs are known in other bacteria as well, *Rhodobacter sphaeroides*, for example. FrzE is a hybrid histidine kinase with catalytic and response regulator domains related respectively to the CheA and CheY chemotaxis proteins of *E. coli*. A second chemotaxis-like signaling system, the Dif system, also contributes to S motility and aggregation in response to lipidic (dioleoyl phosphatidyl ethanolamine) signals released by neighboring cells. It includes DifA, a transmembrane MCP whose extracellular domain seems too small to specifically bind an extracellular water-soluble ligand. The transmembrane domains of DifA may interact directly with specific lipid ligands or indirectly via other macromolecules in the membrane such as the polysaccharide fibrils that adorn the surface of *M. xanthus* cells. Both the fibrils and the lipid seem to be required for aggregation based on S motility. Other proteins of the Dif signaling system controlling S motility are DifE (a CheA homolog) and DifD (a CheY homolog).

The third C-signal transduction pathway involves FruA-mediated induction of the genetic program, leading to sporulation. Phosphorylation of FruA by an unknown upstream histidine kinase leads to induction of FruA∼P-dependent genes such as *devTRS* and repression of genes such as *dofA* whose expression depends upon the unphosphorylated FruA. It is this shift in gene expression at high C-signaling levels that leads to sporulation.

The three C-signaling pathways indicated are able to control the timing of

morphogenesis because they differ in the threshold levels of C-signaling activity required for their activation. Thus, the early, low levels of *csgA* expression are sufficient to activate further expression via the Act proteins. By 6 h of development, the C-signaling levels have reached the threshold for eliciting aggregation. As the cells enter aggregation streams and then form mounds, the level of C-signaling through end-to-end contacts increases to the point where for some of the cells within the mounds sporulation is induced. Other cells within the mounds ultimately undergo autolysis in a form of programmed cell death, while the peripheral rods, cells that failed to enter the aggregates, embark on a completely different program of gene expression. Thus, in *M. xanthus,* it is contact-mediated C-signaling that provides the necessary checkpoints, allowing the extent of morphogenesis to regulate gene expression.

3.1
Cell Cycle Control and Differentiation in *Saccharomyces cerevisiae*

Eukaryotic microorganisms, like their prokaryotic neighbors, face fluctuating levels of nutrients and food supplies in the environment, and, like them, have evolved survival strategies to deal with these uncertainties. The baker's yeast *Saccharomyces cerevisiae* has a choice of different developmental pathways when faced with declining nutrient levels (Fig. 12).

At low nitrogen levels in the presence of an abundant, fermentable carbon source, the normally unicellular, diploid yeast switch to a filamentous form of growth during which the cells elongate, bud at the pole opposite the last site of cytokinesis, and fail to separate from daughter cells after budding. This results in the generation of multicellular pseudohyphae, so called because of their macroscopic similarity to the true hyphae of filamentous fungi or molds, which are composed of multinucleated (coenocytic) tubes of continuous cytoplasm. The pseudohyphal growth form of *Saccharomyces* can be considered a nutrient scavenging mode – the elongated form has a more favorable surface-to-volume ratio for nutrient uptake and the filamentous growth allows penetration of the substratum for potentially better access to nutrient sources.

When both nitrogen and fermentable carbon sources are lacking, diploid yeast cells undergo meiotic divisions to produce a packet (ascus) containing four haploid progeny called *ascospores* – two of each of the mating types **a** and **α**. The process of meiosis provides an opportunity for genetic recombination between the members of each pair of chromosomes in the diploid. Just as is the case for *B. subtilis* cells that become transformation competent, new combinations of genetic information could arise from this process that might better suit their bearers to altered environmental circumstances. The ascospores are resistant to dessication, heat, freezing, and some chemical agents (although not as resistant as bacterial endospores) and can be dispersed in that form to environments more suited to growth. They thus represent a potent survival strategy for yeast cells that have fallen on hard times.

Germination of the ascospores produces haploid yeast cells that are able to grow vegetatively just as the diploid parent did from which they were derived. However, if a nearby cell is of the alternative mating

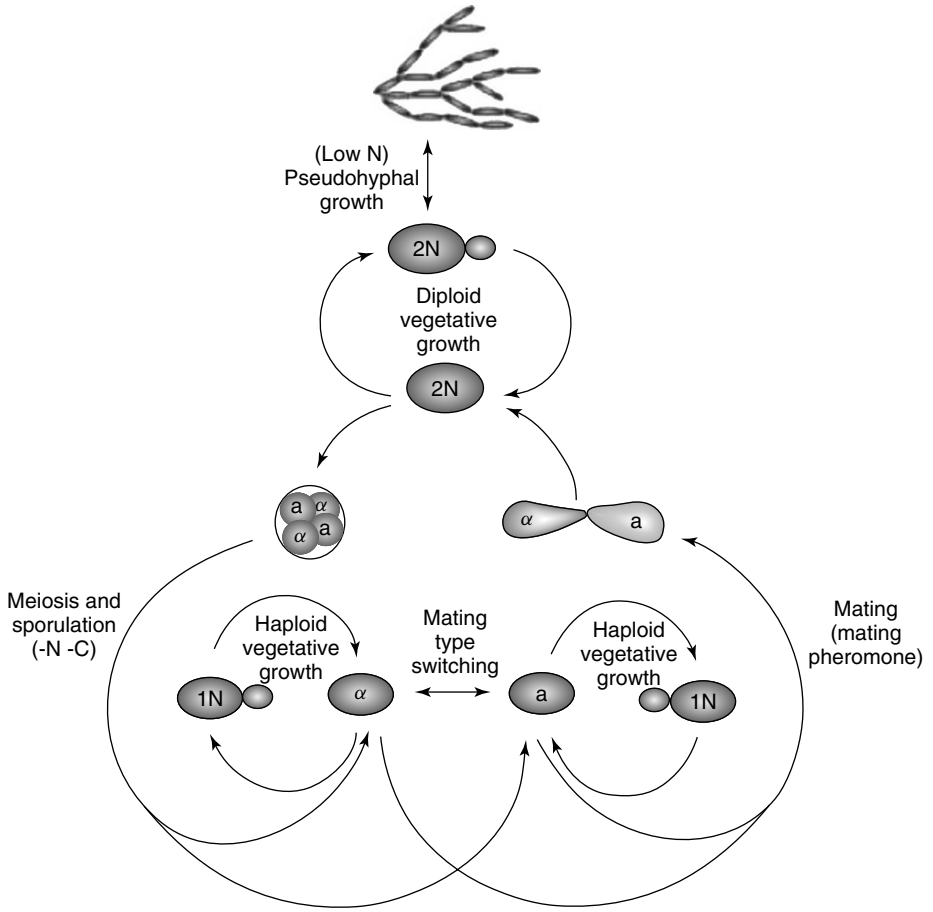

Fig. 12 Cell differentiation during the life cycle of the budding yeast *S. cerevisiae*. In the presence of abundant nutrients, yeast cells can proliferate as either haploid or diploid vegetative cells via a mitotic cell cycle. However, they can differentiate in several ways in response to both internal and environmental cues. Diploid cells, when starved for nutrients, can progress down either of the two pathways of differentiation. Cells starved for nitrogen in the presence of a fermentable carbon source can differentiate into a filamentous form known as *pseudohyphae*, which are capable of invading the substratum. Alternatively, cells starved for nitrogen on a poor carbon source can undergo meiosis and sporulation to generate haploid cells. Haploid cells of both mating types (a and α) can proliferate via a mitotic cell cycle during which they can convert to the other mating type via a programmed DNA rearrangement known as mating-type switching. In addition, when exposed to peptide mating pheromone secreted by cells of the other mating type, haploid cells can differentiate into gametes capable of mating to form a zygote competent to give rise to diploid vegetative cells. From Fig. 1 of Wittenburg, C., La Valle, R. (2003) Cell-cycle-regulatory elements and the control of cell differentiation in the budding yeast, *Bioessays* **25**, 856–867.

type, each of the two haploids responds to a pheromone released by its partner by differentiating into an elongated, pear-shaped gamete called a ''shmoo''. During shmooing, the cells elongate toward one another in a chemotaxis-like process, meet, and fuse to form a new diploid zygote. Additionally, during growth, yeast mother cells that have budded at least once undergo a process called *mating type switching*, whereby copies of the alternate mating type alleles are placed into the mating-type expression site on chromosome III. Thus, even a solitary ascospore that has by misfortune (or by the design of an experimenter!) found itself without sexually compatible neighbors will generate them during growth and go on to produce diploids homozygous at all except the expressed mating-type loci.

3.1.1 Pseudohyphal Growth

Of the two alternative differentiation pathways open to a starving diploid yeast cell, pseudohyphal growth is the less well studied. However, it is clear that one of the fundamental features of this form of growth is an alteration of the cell cycle – the G_1 phase of the cell cycle (following mitotic division (M phase) and preceding DNA replication (S-phase)) is shortened, while the G_2-phase (following S and preceding M) is lengthened. It is the prolonged period of polar cell growth in G_2 that generates the elongated morphology of the cell prior to unipolar budding. This shifting of the cell cycle results from modulation of the two major cell cycle checkpoints controlling entry to the S- and M-phases respectively. As in other eukaryotic cells, these checkpoints are controlled by cyclin-dependent protein kinases (CDKs), which consist of a catalytic (the kinase) and a regulatory subunit (cyclin). In *S. cerevisiae*, a single catalytic subunit, Cdc28, is used in conjunction with several different cyclins, which are employed at different stages of the cell cycle. Three G_1 cyclins (Cln1–3) control passage through G_1 and entry to S, while four mitotic or B-type cyclins (Clb1–4) control entry to and passage through mitosis.

The pathways that induce pseudohyphal growth do so by activating the G_1 cyclins (firstly Cln3, which in turn induces synthesis of Cln1 and Cln2) and inhibiting the mitotic cyclins so that passage through G_1 and entry to S is accelerated, while entry to mitosis at the end of G_2 is delayed (Fig. 13). The two best-studied pathways involve a MAP kinase cascade or cAMP-activated protein kinase A. In the former case, the pathway contains most of the elements involved in mating pheromone responses (see later), but leads to phosphorylation of a different MAP kinase – Kss1. Both pathways lead to activation of transcription factors that would induce expression of G_1 cyclins. In addition to these two pathways, the transcription factor Xbp1 and the cyclin-inhibiting tyrosine kinase Swe1 play roles in filamentation, although precisely how they are integrated into the signaling pathways is not clear.

3.1.2 Meiosis and Sporulation

S. cerevisiae zygotes enter meiosis and sporulation when deprived of both a nitrogen source and a fermentable carbon source. The entry to meiosis depends both upon repression of the G_1 cyclins so that the mitotic cycle is arrested in G_1 and upon induction of the transcription factor Ime1, which elicits transcription of meiosis-specific genes (Fig. 14). Both are a response to starvation, but Ime1 is expressed only in diploid cells heterozygous at the mating type locus (i.e. *MAT***a**/**α**). This is

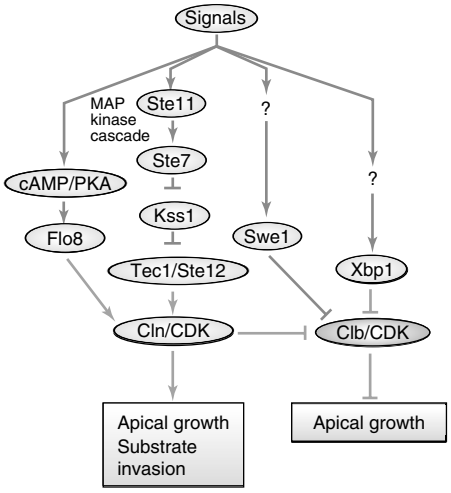

Fig. 13 Proposed pathways regulating cyclin-dependent kinases during pseudohyphal differentiation in *Saccharomyces cerevisiae*. From the nutritional signals that elicit filamentation, the pathways proceed via activation of a MAP kinase phosphorylation cascade, cAMP-activated protein kinase (PKA), Swe1 tyrosine protein kinase (a Cln/CDK inhibitor), or the stress-induced transcription factor Xbp1. Ste11 is the yeast equivalent of mammalian MAPKKK (MAPKK kinase), Ste7 the equivalent of MAPKK (MAPK kinase) and Kss1 is a MAP kinase (MAPK). Flo8 and Tek1/Ste12 are transcription factors. Unphosphorylated Kss1 inhibits Ste12 and its phosphorylation relieves this inhibition. Flo8 and Tek1/Ste12 are transcription factors. The pathways activating Swe1 and Xbp1 are uncertain and both may be coupled to the MAP kinase pathway. A variety of other proteins whose activities influence CDK activities also have corresponding effects on filamentation. Green ellipses indicate proteins whose activity stimulates apical growth, while red ellipses indicate proteins whose activity inhibits it. Arrowheads indicate stimulatory interactions and barred ends indicate inhibitory interactions. Blue arrows stand for interactions at the transcriptional level (gene induction or repression) and red arrows stand for interactions at the protein level (activation or inhibition). (See color plate. p. xxix)

because, in haploid cells, the transcriptional regulator Rme1 is active, both in repressing *IME*1 expression and in inducing G_1 cyclin expression. *IME*1 expression is also repressed by the G_1 CDKs containing cyclins Cln1 or Cln2 (Cln1–2/CDKs). In addition, Cln1–2/CDKs inhibit the nuclear localization of Ime1 with the result that it cannot interact with target DNA sequences. Accordingly, only starving, diploid cells embark upon meiosis.

During mitotic growth of both haploids and diploids, *IME*1 expression is repressed partly by Cln1–2/CDKs and partly by the transcriptional regulator SBF (which also induces the G_1 cyclins). Under these same conditions, the Ime1 polypeptide is also inactivated by virtue of being excluded from the nucleus and being inhibited from interacting with its transcriptional coactivator Ume6. Thus, mitotic growth and meiotic sporulation are mutually exclusive.

Amongst the genes whose expression is induced by Ime1/Ume6 upon entry into meiosis is *IME*2, which encodes a meiosis-specific protein kinase. *Ime2* phosphorylates and so promotes the proteolytic destruction of Sic1, an inhibitor of mitotic CDKs containing the cyclins Clb5 and Clb6 (Clb5–6/CDKs). At the same time, Ime2 activates Ndt80, the major transcriptional activator of *CLB*1–6 expression. As a result of these two activities of Ime1, the B-type cyclins are activated and elicit progression through the events of meiosis, including DNA replication, synapsis/recombination, and meiotic division. Along the way, Swe1 functions as a checkpoint kinase to inhibit Clb1–4/CDKs and meiotic progression until chromosome synapsis and recombination events are completed properly.

Swe1 also plays a checkpoint role in mitosis, restricting progression until

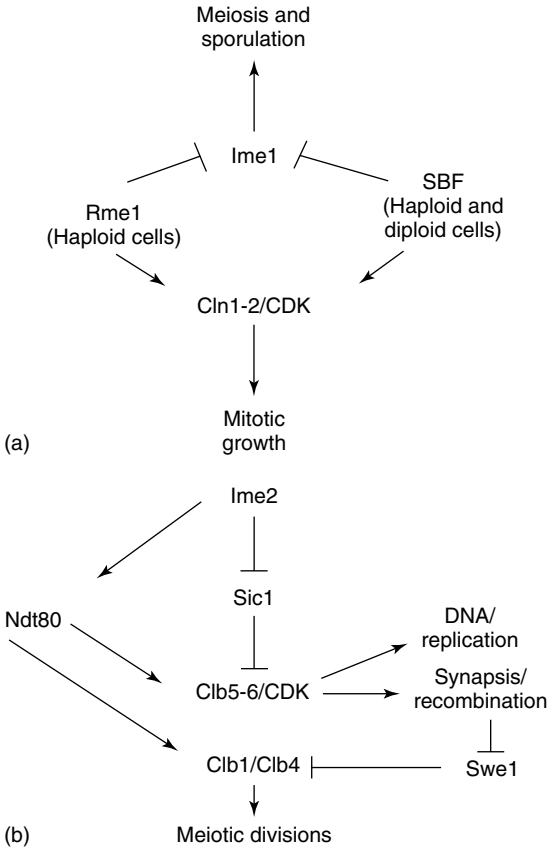

Fig. 14 Regulation of cyclin-dependent protein kinase (CDK) during meiosis and sporulation. Diploid cells undergo meiosis and sporulation when starved for nitrogen and a fermentable carbon source, but grow vegetatively when both nitrogen and carbon sources are abundant. A: Ime1, the primary inducer of meiosis-specific genes, and G1 cyclins, which promote entry into the mitotic cell cycle are subject to differential regulation by the Rme1, a haploid-specific repressor of meiosis, and SBF, the primary G1-specific transcriptional activator. B: The primary repressor of B type cyclin/CDK activity during meiosis, Sic1, and the major transcriptional activator of CLB genes, Ndt80, are differentially regulated by the meiosis-specific protein kinase Ime2. Clb-associated CDKs are also subject to inhibition by the Swe1 protein kinase until synapsis and recombination are complete. From Fig. 2 of Wittenburg, C., La Valle, R. (2003) Cell-cycle-regulatory elements and the control of cell differentiation in the budding yeast, *Bioessays* **25**, 856–867.

the actin cytoskeleton is properly assembled in preparation for budding and, as noted above, it monitors filamentation signals during pseudohyphal growth. How it monitors these disparate signals is not known and is one example of the gaps in our understanding of yeast cell differentiation pathways that remain to be filled.

3.1.3 One Locus, Three Cell Types

The result of meiotic sporulation is an ascus containing four haploid ascospores, two of each mating type (**a** and $\boldsymbol{\alpha}$), derived from one parental diploid cell. When it germinates, each haploid cell can begin vegetative growth and mitotic proliferation. However, the presence of mating pheromones from cells of the opposite mating type will induce further differentiation – gametogenesis or shmooing – as a prelude to mating. For this to occur, the cells of each mating type must synthesize and release its corresponding pheromone and must also express a receptor for the pheromone of the opposite mating type. In other words, vegetatively growing yeast cells can be one of three distinct cell types – diploid, haploid **a**, and haploid $\boldsymbol{\alpha}$. The different patterns of gene expression in these three cell types result from the expression of

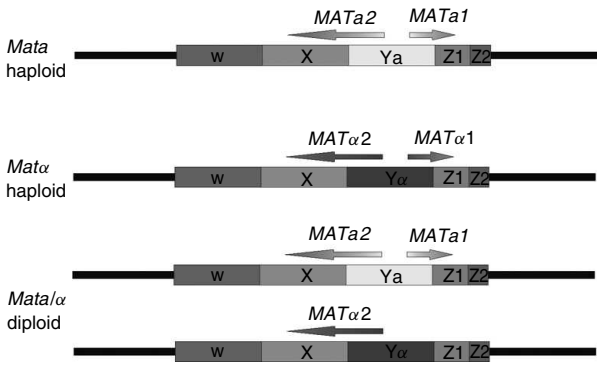

Fig. 15 The mating-type locus in *Saccharomyces cerevisiae*. The locus on Chromosome III can be divided into five regions on the basis of their presence in the two mating type alleles, *MAT*a and *MAT*α, and in the two silent copies on the left (*HML*) and right (*HMR*) arms of Chromosome III. The two *MAT* alleles differ only in the approximately 700 bp region Y, which thus has two alleles Ya and Yα. Each of the Y-regions contains divergent promoters for two transcripts, as indicated by the arrows. Most of the coding sequence of the encoded polypeptides is contained within the Y-region. The *MAT*α1 transcript is repressed in the *MAT*a/α diploid by the Mata1/Matα2 heterodimer. The X and Z1 regions are shared with *HMR*, while the W and Z2 regions are shared with *HML*. These provide regions of sequence identity that promote the strand alignment and annealing involved in the gene conversions that lead to mating type switching.

mating type–specific transcription factors encoded by the mating type alleles in residence at the mating-type (*MAT*) locus on chromosome III.

The genetic configuration of the mating-type locus in each of these three cell types is shown in Fig. 15. As described in the previous section, in haploid cells, the transcriptional repressor Rme prevents expression of Ime and diploid-specific genes. However, *RME* expression is itself repressed in the diploid by a heterodimer of the Mat**a**1 corepressor and the Mat**α**2 homeodomain DNA-binding protein. Cells of the two haploid mating types owe their differences to the activities of the *MAT***α** gene products in combination with the Mcm1 polypeptide – Mat**α**2/Mcm1 represses **a**-specific genes, while Mat**α**1/Mcm1 induces the expression of **α**-specific genes. In a haploid **a** cell, neither of the *MAT***α** gene products is present so that the constitutive state prevails – **a**-specific genes are expressed and **α**-specific genes are not. Mat**a**2 has no known function, while Mat**a**1 exerts its function only in the diploid state where it can combine with Mat**α**2.

3.1.4 Gametogenesis and Mating

The process of gametogenesis leading to mating is induced in haploid **a** and **α** cells by pheromones secreted by neighboring cells of the opposite mating type. The pheromones bind to their cognate receptors (Ste2 for the **α**-factor, Ste3 for the **a**-factor) of the ubiquitous eukaryotic GPCR

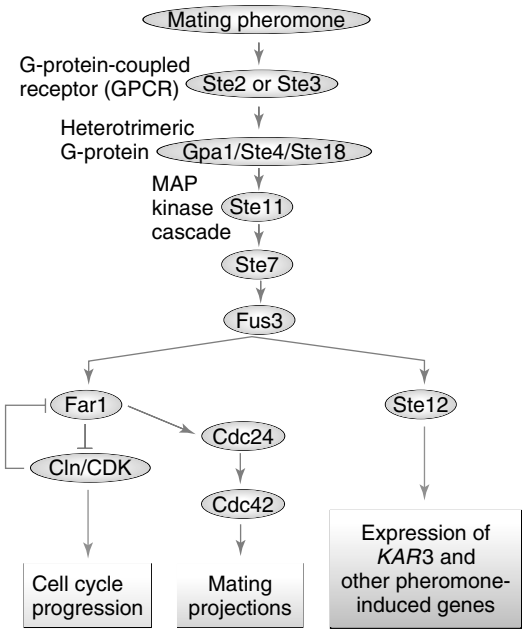

Fig. 16 Signal transduction pathways controlling gametogenesis in *Saccharomyces*. Binding of the pheromone to its cognate receptor (Ste2 = α factor receptor, Ste3 = a factor receptor) causes a conformational change and dissociation of the heterotrimeric G-protein (Gpa1 = α subunit, Ste4 = β subunit, Ste18 = γ subunit). The Ste4/Ste18 ($\beta\gamma$) heterodimer activates Ste20 a serine/threonine protein kinase, which initiates the MAP kinase phosphorylation cascade. Ste11 (MAPKKK), Ste7 (MAPKK) and Fus3 (MAPK) are each in their turn phosphorylated by the preceding kinase and thereby activated. At the end of the phosphorylation cascade, Fus3 phosphorylates and activates the Cln/CDK inhibitor Far1 as well as the transcription factor Ste12. As described in the text, the former causes cell cycle arrest in G1 and formation of mating projections, while the latter causes pheromone-inducible gene expression. Arrowheads indicate stimulatory interactions and barred ends indicate inhibitory interactions. Blue arrows stand for interactions at the transcriptional level (gene induction or repression) and red arrows stand for interactions at the protein level (activation or inhibition). (See color plate. p. xxxi)

(G-protein-coupled receptor) family and thereby elicit dissociation of the α and $\beta\gamma$ subunits of the associated G-protein. The $G_{\beta\gamma}$ heterodimer released in this way then interacts with and activates the Ste20 protein kinase, which phosphorylates Ste11, a MAPKK kinase (MAPKKK). The ensuing phosphorylation cascade culminates in activation of the MAP kinase Fus3, which, in turn, phosphorylates and activates two target proteins – the transcription factor Ste12 and the CDK inhibitor Far1 (Fig. 16).

Ste12∼P initiates the characteristic pheromone-dependent changes in gene expression that accompany gametogenesis. For example, pheromone treatment induces a 20-fold increase in the expression of *KAR*3, which encodes a kinesin-like motor protein required for nuclear fusion. At the same time, Far1 that has been phosphorylated by Fus3 inhibits the G_1 CDKs – both Cln3/CDK-mediated induction of Cln1,2 expression and Cln1–2/CDK activities are suppressed, so that the cell cycle arrests in G1-phase. In addition, Far1∼P binds to and activates Cdc24, a GTP exchange factor (GEF) for the small GTP-binding protein Cdc42. This promotes release of GDP and binding of GTP to Cdc42, activating its role in actin filament recruitment to and promotion of the mating projections that lend shmoos their characteristic elongated morphology. Cdc42 also plays an important role in actin recruitment during budding of vegetatively growing cells.

As is the case with so many critical developmental events, Far1 activation is coupled to the cell cycle and is autocatalytic. Thus, *FAR*1 expression is limited to G1

and is induced severalfold by pheromone signaling. Furthermore, the Far1 protein is also phosphorylated by Cln/CDK, an event that promotes its ubiquitination and proteolytic degradation. By inhibiting Cln/CDK activity, Far1 thus facilitates its own stabilization in G1. After G1, when Cln/CDK levels are high, the protein becomes labile because of its CDK-mediated phosphorylation. This pattern of regulation means that Far1-mediated gametogenesis and mating are restricted to G1. Mutants that lack Far1 still exhibit normal pheromone-induced gene expression because of Ste12 activation, but gametogenesis and mating are impaired. Restricting mating to G1 coordinates it with nuclear events, ensures that each mating partner contributes a single spindle polar body (SPB) for participation in nuclear fusion, and guarantees correct stable ploidy after fusion of nuclei in the zygote. Furthermore, the formation of the mating projection in a shmoo may be effective only in G1 when the cell is not budding.

3.1.5 Silent Copies of the Mating-type Alleles and Mating-type Switching

In homothallic yeast strains, mating can occur in a clonal population of cells derived from a single haploid ascospore. This occurs because of the phenomenon of mating-type switching whereby experienced mother cells (i.e. those that have budded at least once) switch mating types before budding again. Mating-type switching involves copying the mating-type allele present at one of the silent loci *HML* or *HMR* into the mating-type locus *MAT* to replace the existing alleles at that site

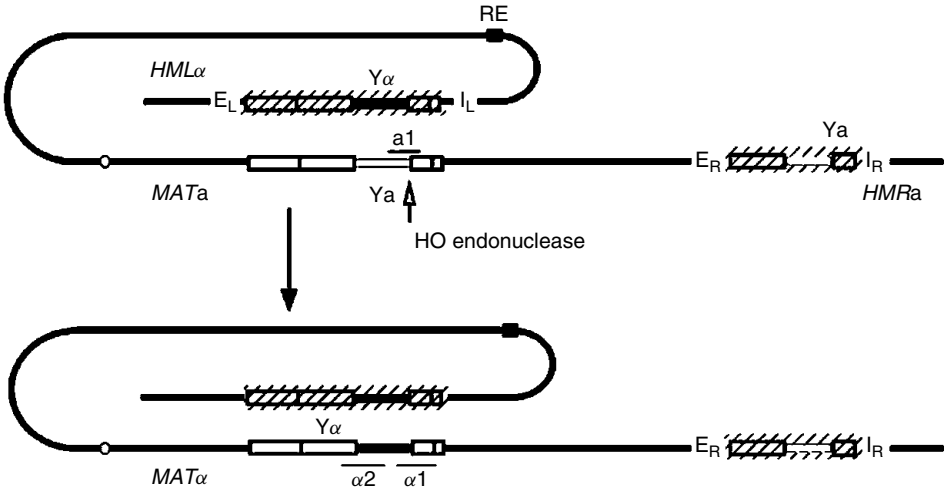

Fig. 17 Mating-type switching at the *MAT*a locus. The HO endonuclease creates a double-strand break at the Y/Z1 border of the *MAT* locus and initiates gene conversion by using the silent donor. The two donor loci (*HML* and *HMR*) are maintained in a transcriptionally inactive chromatin structure (indicated by diagonal stripes). Other shared regions of homology are indicated. The preference for the *HML* donor in *MAT*a cells is mediated by the recombination enhancer (RE) region located ~17-kb centromere-proximal to *HML*. The positions of *HML*, RE, the centromere (○), *MAT*, and *HMR* are indicated. Figure kindly provided by Prof. J.E. Haber, Brandeis University (http://www.bio.brandeis.edu/haberlab/jehsite/donorprf.html).

(Fig. 17). Unlike *MAT, HML* and *HMR* are each flanked by a pair of related, but distant silencer regions – *HML*-E, *HML*-I, *HMR*-E, *HMR*-I – sequences, which are binding sites for a complex of proteins that collaborate to produce a transcriptionally silent region of about 3 kb of highly ordered heterochromatin between the E and the I silencer sequences. These proteins include Sir1–4 (silent information regulator proteins), DNA-binding proteins Rap1 and Abf1, proteins of the origin recognition complex (ORC), which assemble at DNA replication origins, protein *trans*-acetylases and deacetylases, and chromatin assembly factors.

Each of the four silencer regions is able to act as an origin of replication when placed into an extrachromosomal plasmid, but does not function as such normally. Thus, although the ORC proteins in this case are needed for silencing, they do not normally initiate replication at these sites. The Sir proteins do not bind directly to the DNA, but bind indirectly via other DNA-binding proteins in the complexes. The Sir proteins also play other roles in the cells – in gene silencing at telomeres, in maintaining mitotic chromatin structure, in limiting rates of recombination, and in stabilizing rDNA. These functions also have repercussions for cell longevity – Sir proteins promote longevity in yeast cells and Sir2-like proteins (sirtuins – NAD^+-dependent deacetylases) do the same in animals. These and many other proteins are required for or affect silencing, enhancing, or weakening it, and their roles are not all understood.

Because of the transcriptional silencing of the *HML* and *HMR* loci, only the mating-type alleles at the *MAT* locus are expressed and thus control the gene expression patterns associated with the haploid mating type or with diploidy (see earlier). The switching of mating types that occurs in homothallic yeast strains is initiated by the activity of HO, a site-specific endonuclease that recognizes a 24-bp sequence at the border of the Y-region with the Z-region in *MAT* (Fig. 15). The silencing of *HML* and *HMR* also protects them from recognition and cleavage by HO, so that only the *MAT* locus is cut to leave a 4-bp, 3′-overhang on each side of the cleavage site. The 3′ ends are resistant *in vivo* to exonucleolytic digestion, but the 5′-ends are processed by 5′ to 3′ exonuclease activity, which includes a trio of interacting proteins (Rad50, Mre11, and Xrs2). This yields long, single stranded 3′ tails both sides of the cut site, one of which extends through the Y-region and the other of which extends through the Z-region. The latter invades the homologous region of *HML* or *HMR*, as the case may be, where it is extended across the HO cut site through the Y-region using the silent alleles as template, replicated and subsequently used to displace the remaining 3′ tail at the *MAT* locus. The nonreciprocal nature of this gene conversion means that a copy of the silent alleles has now replaced the original alleles at the *MAT* locus.

Because there are two silent loci containing mating-type alleles, the process of mating-type conversion involves a selection of either *HML* or *HMR* as the donor locus. This selection is not random – *MAT***a** cells almost always use *HML* as the donor and *MAT*$\boldsymbol{\alpha}$ cells use *HMR*. Since the great majority of strains carry $\boldsymbol{\alpha}$ alleles at *HML* and **a** alleles at *HMR*, this results in high rates of mating-type switching. This donor selectivity results from activation of the left (*HML*) end of chromosome III for mating-type donation (and for recombination) in *MAT***a** cells and its inactivation in *MAT*$\boldsymbol{\alpha}$ cells

(making *HMR* the only donor available). A 270-bp sequence called *RE* (recombination enhancer) that is responsible for donor selectivity has been identified on the left arm of chromosome III, 17 kb to the right of *HML*. This 270-bp sequence contains four regions (A to D) that are highly conserved amongst different *Saccharomyces* species.

Region C of *RE* includes a consensus binding site, an operator sequence, to which the Matα2/Mcm1 repressor binds. At other such sites in the genome, this represses the expression of nearby **a**-specific genes, but, in this case, in conjunction with the Tup1 and Ssn6 proteins, it inactivates *HML* selection, suppresses other recombinational events in the region, and elicits the assembly of a chromatin structure with tightly phased nucleosomes. In *MAT***a** cells, with Matα2 absent, Mcm1 binds to the same site and activates the region for recombination and *HML* selection. Thus, a 2-bp mutation in the operator eliminates the ability of Mcm1 to bind to it and abolishes the preference for *HML* in *MAT***a** cells. Furthermore, a mutant Mcm1 with reduced ability to bind to the operator also impairs *HML* preference in *MAT***a** cells.

Regions A and D, as well as another nearby sequence region (designated E), have been found to contain sites for *in vivo* binding of two transcriptional activators – the forkhead proteins Fkh1 and Fkh2 and the associated protein Ndd1. As is the case for the Mcm1 site in Region C, the Fkh1/Fkh2 binding sites in Regions A, D, and E do not function in transcription regulation, but in activation of *HML* donor preference.
